Combined measurements of Higgs boson production and decay using up to 80 fb$^{-1}$ of proton-proton collision data at $\sqrt{s} = 13$ TeV collected with the ATLAS experiment

G. Aad et al. (*)
(ATLAS Collaboration)

(Received 9 September 2019; published 3 January 2020)

Combined measurements of Higgs boson production cross sections and branching fractions are presented. The combination is based on the analyses of the Higgs boson decay modes $H \rightarrow \gamma\gamma$, $ZZ^*$, $WW^*$, $\tau\tau$, $bb$, $\mu\mu$, searches for decays into invisible final states, and on measurements of off-shell Higgs boson production. Up to 79.8 fb$^{-1}$ of proton–proton collision data collected at $\sqrt{s} = 13$ TeV with the ATLAS detector are used. Results are presented for the gluon–gluon fusion and vector-boson fusion processes, and for associated production with vector bosons or top-quarks. The global signal strength is determined to be $\mu = 1.11^{+0.09}_{-0.08}$. The combined measurement yields an observed (expected) significance for the vector-boson fusion production process of 6.5$\sigma$ (5.3$\sigma$). Measurements in kinematic regions defined within the simplified template cross section framework are also shown. The results are interpreted in terms of modifiers applied to the Standard Model couplings of the Higgs boson to other particles, and are used to set exclusion limits on parameters in two-Higgs-doublet models and in the simplified minimal supersymmetric Standard Model. No significant deviations from Standard Model predictions are observed.

I. INTRODUCTION

Following the discovery of the Higgs boson $H$ [1–6] by the ATLAS [7] and CMS [8] experiments, its properties have been probed using proton–proton ($pp$) collision data produced by the Large Hadron Collider (LHC) at CERN. The coupling properties of the Higgs boson to other Standard Model (SM) particles, such as its production cross sections in $pp$ collisions and decay branching fractions, can be precisely computed within the SM, given the value of the Higgs boson mass. Measurements of these properties can therefore provide stringent tests of the validity of the SM.

Higgs boson production and decay rates have been determined using the Run 1 dataset collected in the years 2011 and 2012, through the combination of ATLAS and CMS measurements [9]. More recently, these measurements have been extended using the Run 2 dataset recorded by the ATLAS detector in 2015, 2016 and 2017, using up to 79.8 fb$^{-1}$ of $pp$ collision data produced by the LHC. The analyses target several production and decay modes, including: the $H \rightarrow \gamma\gamma$ and $H \rightarrow ZZ^* \rightarrow 4\ell^\pm$ decay channels following the same methodologies as those presented in Ref. [10] and Ref. [11] respectively, with improved selections for Higgs boson production in association with a top–antitop pair, described in Ref. [12]; the $H \rightarrow WW^*$ [13] and $H \rightarrow \tau\tau$ [14] decay channels; $H \rightarrow bb$ in associated production with a weak vector boson $V = W$ or $Z (VH)$ [15,16] and in the weak vector-boson fusion (VBF) production process [17]; associated production with a top–antitop pair ($t\bar{t}H$) [12,18,19]; the $H \rightarrow \mu\mu$ decay channel following the same methodology as presented in Ref. [20], applied to the larger 2015–2017 input dataset; Higgs decays into invisible final states [21–24]; and off-shell production of Higgs bosons [25]. This paper presents measurements of Higgs boson properties at $\sqrt{s} = 13$ TeV obtained from the combination of these results, using techniques similar to those in Ref. [9]. A Higgs boson mass value of $m_H = 125.09$ GeV, corresponding to the central value of the combination of ATLAS and CMS measurements in Run 1 [26], is used for SM predictions. The uncertainty in the measured Higgs boson mass is considered in the $H \rightarrow \gamma\gamma$ and $H \rightarrow ZZ^* \rightarrow 4\ell^\pm$ analyses. Similar measurements [27–33], as well as their combination [34], have been reported by the CMS Collaboration.

All the input analyses except those for the $H \rightarrow \mu\mu$ and the VBF, $H \rightarrow bb$ processes use a parametrization of the Higgs boson signal yields based on the Stage 1 simplified template cross section (STXS) framework [35,36] described in Sec. VI A. These cross sections are

1Throughout the paper $\ell$ denotes the light leptons $e$ and $\mu$.
defined in the fiducial region $|y_H| < 2.5$, where $y_H$ is the Higgs boson rapidity, partitioned within each Higgs boson production process into multiple kinematic regions based on the transverse momentum of the Higgs boson, the number of associated jets, and the transverse momentum of associated $W$ or $Z$ bosons. The $H \rightarrow \mu\mu$ and VBF, $H \rightarrow bb$ analyses use a coarser description based on the Higgs boson production mode only.

The paper is structured as follows: Section II describes the data and simulation samples and Sec. III presents the analyses in individual decay channels which are used as inputs to the combination. Section IV provides a short description of the statistical procedures. The measurement of the signal strength $\mu$, defined as the ratio of the total Higgs boson signal yield to its SM prediction, is presented in Sec. VA. Measurements of the cross sections of the main production processes within $|y_H| < 2.5$, assuming SM predictions for the branching fractions, are then shown in Sec. VB. The production modes considered are gluon–gluon fusion ($ggF$), VBF, $VH$, $t\bar{t}H$ and associated production with a single top quark ($t\bar{t}H$). Measurements of cross sections times branching fractions for Higgs boson production and decay processes are shown in Sec. VC. Section VD presents a parametrization where the measured quantities are the cross section times branching fraction of the process $gg \rightarrow H \rightarrow ZZ^*$, together with ratios of production cross sections and ratios of branching fractions. Common systematic uncertainties and modeling assumptions partially cancel out in these ratios, reducing the model dependence of the result. Section VI presents results in the STXS framework. Potential deviations from SM predictions are then probed in a framework of multiplicative modifiers $\kappa$ applied to the SM values of Higgs boson couplings [37], presented in Sec. VII. Finally, Sec. VIII presents an interpretation of the data within two benchmark models of beyond-the-SM (BSM) phenomena. Indirect limits on model parameters are set following a methodology similar to that of Ref. [38]. Section IX summarizes the results.

II. DATA AND SIMULATED EVENT SAMPLES

The results of this paper are based on $pp$ collision data collected by the ATLAS experiment\textsuperscript{2} [39–41] in the years 2015, 2016 and 2017, with the LHC operating at a center-of-mass energy of 13 TeV. The integrated luminosities of the datasets used in each analysis are shown in Table I. The uncertainty in the combined 2015–2016 integrated luminosity is 2.1\% and 2.0\% in the combined 2015–2017 integrated luminosity [42], obtained using the LUCID-2 detector [43] for the primary luminosity measurements.

Most analyses use a consistent set of simulated Higgs boson samples to describe the signal processes, which is detailed in the following paragraphs. Exceptions are the VBF, $H \rightarrow bb$ and off-shell production analyses, described in Secs. III E and III I respectively, and the measurements targeting decays of the Higgs boson into invisible final states described in Sec. III H. The samples used for these analyses are described separately at the end of this section. For each Higgs boson decay mode, the branching fraction used corresponds to higher-order state-of-the-art theoretical calculations [35]. The simulated background samples vary channel by channel and are described in the individual references for the input analyses.

Higgs boson production via gluon–gluon fusion was simulated using the POWHEG BOX [44–47] NNLOPS implementation [48,49]. The event generator uses the HNNLO formalism [50] to reweight the inclusive Higgs boson rapidity distribution produced by the next-to-leading order (NLO) generation of $pp \rightarrow H + \text{parton}$, with the scale of each parton emission determined using the MINLO procedure.
The PDF4LHC15 [54] parton distribution functions (PDFs) were used for the central prediction and uncertainty. The sample is normalized such that it reproduces the total cross section predicted by a next-to-next-to-leading-order (N^2LO) QCD calculation with NLO electroweak corrections applied [35,55–64]. The NNLOPS generator reproduces the Higgs boson p_T distribution predicted by the next-to-next-to-leading-order (NNLO) plus next-to-next-to-leading-logarithm (NNLL) calculation of HRES2.3 [65–67], which includes the effects of top- and bottom-quark masses and uses dynamical renormalization and factorization scales.

The VBF production process was simulated to NLO accuracy in QCD using the POWHEG BOX [68] generator with the PDF4LHC15 set of PDFs. The sample is normalized to an approximate-NNLO QCD cross section with NLO electroweak corrections applied [35,69–71].

The gg → VH production processes were simulated to NLO accuracy in QCD using the POWHEG BOX, GOSAM [72] and MINLO [51,73] generators with the PDF4LHC15 set of PDFs. The samples are normalized to cross sections calculated at NNLO in QCD with NLO electroweak corrections [74–83]. The gg → ZH process was generated only at leading order (LO), using POWHEG BOX and NLO PDFs and normalized to an NLO computation with next-to-leading-logarithm (NLL) corrections [35,84].

Higgs boson production in association with a top–antitop pair was simulated at NLO accuracy in QCD using the POWHEG BOX [85] generator with the PDF4LHC15 set of PDFs for the H → γγ and H → ZZ → 4ℓ decay processes. For other Higgs boson decays, the MADGRAPH5_AMC@NLO [86,87] generator was used with the NNPDF3.0 [88] set of PDFs. In both cases the sample is normalized to a calculation with NLO QCD and electroweak corrections [35,89–92].

In addition to the primary Higgs boson processes, separate samples are used to model lower-rate processes. Higgs boson production in association with a b¯b pair (b¯bH) was simulated using MADGRAPH5_AMC@NLO [93] with NNPDF2.3LO PDFs [94] and is normalized to a cross section calculated to NNLO in QCD [35,95–97]. The sample includes the effect of interference with the ggF production mechanism. Higgs boson production in association with a single top quark and a W boson (tHW) was produced at LO accuracy using MADGRAPH5_AMC@NLO with the CTEQ6L1 PDF set [98]. Finally, Higgs boson production in association with a single top quark in the t-channel (tHq) was generated at LO accuracy using MADGRAPH5_AMC@NLO with CT10 [99] PDFs. The tH samples are normalized to NLO QCD calculations [35,100,101].

The parton-level events were input to PYTHIA8 [102] or HERWIG++ [103] to model the Higgs boson decay, parton showering, hadronization, and multiple parton interaction (MPI) effects. The generators were interfaced to PYTHIA8 for all samples except tHW. For PYTHIA8 the AZNLO [104] and A14 [105] parameter sets were used, and for HERWIG++ its UEHE5 parameter set was used.

Higgs boson decay branching fractions were computed using HEDECAY [106–108] and PROPEH24 [109–111].

In the all-hadronic channel of the VBF, H → b̄b analysis, the POWHEG BOX generator with the CT10 [99] set of PDFs was used to simulate the ggF [112] and VBF production processes, and interfaced with PYTHIA8 for parton shower. In the photon channel of the VBF, H → b̄b analysis, VBF and ggF production in association with a photon was simulated using the MADGRAPH5_AMC@NLO generator with the PDF4LHC15 set of PDFs, and also using PYTHIA8 for parton shower. For both channels, contributions from VH and tH production were generated using the PYTHIA8 generator with the NNPDF3.0 set of PDFs, and using the MADGRAPH5_AMC@NLO generator interfaced with HERWIG++ and the NLO CT10 set of PDFs, respectively.

In the analyses targeting Higgs boson decays into invisible final states, the ggF, VBF and ZH signals were simulated in a similar way to the general procedure described above, but for the VBF production process the NNPDF3.0 PDF set was used instead of PDF4LHC15, while for the ZH process the CT10 PDF set was used.

In the off-shell production analysis, the gg → H* → ZZ process was generated together with the corresponding irreducible continuum production, using the SHERPA2.2.1 + OPENLOOPS [113–116] generator and the NNPDF3.0 PDF set. The generation was performed at leading order with up to one additional jet in the final state, and interfaced with the SHERPA parton shower [117]. The cross section calculations take into account K-factors following the methodology described in Ref. [25].

The particle-level Higgs boson events were passed through a GEANT 4 [118] simulation of the ATLAS detector [119] and reconstructed using the same analysis software as used for the data. Event pileup is included in the simulation by overlaying inelastic pp collisions, such that the average number of interactions per bunch crossing reproduces that observed in the data. The inelastic pp collisions were simulated with PYTHIA8 using the MSTW2008LO [120] set of PDFs with the A2 [121] set of tuned parameters or using the NNPDF2.3LO set of PDFs with the A3 [122] set of tuned parameters.

III. INDIVIDUAL CHANNEL MEASUREMENTS

Brief descriptions of the input analyses to the combination are given below. More details can be found in the individual analysis references listed in each section. The categorization is summarized in Table II. The overlap between the event selections of the analyses included in the combination is found to be negligible.

A. H → γγ

The H → γγ analysis [10,12] requires the presence of two isolated photons [123] within the pseudorapidity range |η| < 2.37, excluding the region 1.37 < |η| < 1.52.

</table>
corresponding to the transition between the barrel and endcap sections of the electromagnetic calorimeter. The transverse momenta of the leading and subleading photons are required to be greater than 0.35$m_{\gamma\gamma}$ and 0.25$m_{\gamma\gamma}$ respectively, where $m_{\gamma\gamma}$ is the invariant mass of the diphoton system. The event reconstruction and selection procedures are largely unchanged from the ones described in Ref. [10]. The only significant change concerns the reconstruction of the calorimeter energy clusters associated with the photons; a dynamical, topological cell clustering-based algorithm [124,125] is now used instead of a sliding-window technique [123,126].

Selected events are separated into 29 mutually exclusive categories based on the kinematics of the diphoton system and associated particles, chosen to approximately match those of the Stage 1 STXS regions described in Sec. VI A. Seven categories are defined to select $t\bar{t}H$ production, including both semileptonic and hadronic top-quark decay processes through various selections on the multiplicities and kinematics of leptons [127–129], jets [130], and jets tagged as containing $b$-hadrons [131]. These categories are described in Ref. [12]. The remaining events are classified into categories targeting the VH, VBF and ggF production modes, described in Ref. [10]. Five categories are defined to select $WH$ and $ZH$ production with leptonic decays of the $W$ or $Z$, based on the presence of leptons and missing transverse momentum $E_T^{miss}$ [132]. Seven categories cover the VBF and VH processes: one category requires the presence of two jets, with the leading jet transverse momentum $p_T^{j1} > 200 \text{ GeV}$; two categories select hadronic vector-boson decays by requiring two jets with an invariant mass compatible with the $W$ or $Z$ boson mass; and four categories enrich VBF production by requiring forward jets in a VBF-like topology. The requirement of a second jet for the $p_T^{j1} > 200 \text{ GeV}$ category is a change compared to Ref. [10] where only one jet was required, and helps to reduce contamination from ggF production. The remaining events are split into 10 categories, separating events with 0, 1, and ≥2-jets and classifying them further according to the pseudorapidity of the two photons (for 0-jet events) or the transverse momentum of the diphoton system $p_T^{\gamma\gamma}$ (for 1 and ≥2-jet events). The distribution of $m_{\gamma\gamma}$ is used to separate the Higgs boson signal from continuum background processes in each category.

B. $H \rightarrow ZZ^\ast \rightarrow 4\ell$

The $H \rightarrow ZZ^\ast \rightarrow 4\ell$ analysis requires the presence of at least two same-flavor and opposite-charge light-lepton pairs, with a four-lepton invariant mass $m_{4\ell}$ in the range $115 \text{ GeV} < m_{4\ell} < 130 \text{ GeV}$. The analysis follows the strategy described in the previous publication [11], but employs improved event reconstruction and electron reconstruction [125] techniques, and defines additional event categories to enhance sensitivity to the production of the SM Higgs boson associated with a vector boson ($VH, V \rightarrow \ell\nu/\ell\overline{\nu}$) and with a top-quark pair [12].

To distinguish the $t\bar{t}H$, VH, VBF, and ggF production modes and to enhance the purity of each kinematic selection, 11 mutually exclusive reconstructed event categories based on the presence of jets and additional leptons in the final state are defined. Candidate events with at least one $b$-tagged jet and three or more additional jets, or one additional lepton and at least two additional jets are classified into categories enriched in $t\bar{t}H$ production with fully hadronic or semileptonic top-quark decays respectively [12]. Events failing these requirements but containing at least one additional lepton are assigned to a VH-enriched category with leptonic vector boson decays. The remaining events are classified according to their jet multiplicity (0-jet, 1-jet, and ≥2-jet). Events with at least two jets are divided into a VBF-enriched region, for which the dijet invariant mass $m_{jj}$ is required to be above 120 GeV, and a region enriched in VH events with a hadronically decaying vector boson for $m_{jj} < 120 \text{ GeV}$.

The VBF-enriched region is further split into two categories, in which the transverse momentum of the leading jet $p_T^{j1}$ is required to be either above or below 200 GeV. The selected 0-jet and 1-jet events are further separated according to the transverse momentum $p_T^{4\ell}$ of the four-lepton system: the 0-jet events are split into two categories with a boundary at $p_T^{4\ell} = 100 \text{ GeV}$, with the lower $p_T^{4\ell}$ selection being enriched in Higgs boson events produced via ggF and the higher $p_T^{4\ell}$ selection being enriched in Higgs boson events produced in association with a weak vector boson. The 1-jet events are split into three categories, each containing predominantly Higgs boson events produced via ggF, with boundaries at $p_T^{4\ell} = 60$ and 120 GeV to match the STXS selections described in Sec. VI A. Boosted decision trees (BDTs) are employed to separate the signal from the background processes and to enhance the sensitivity to the various Higgs boson production modes.

C. $H \rightarrow WW^\ast \rightarrow e\nu\mu\nu$

The $H \rightarrow WW^\ast \rightarrow e\nu\mu\nu$ analysis [13] included in the combination targets the ggF and VBF production modes. Signal candidates are selected by requiring the presence of an isolated $e^{\pm}\mu^{\mp}$ pair, with transverse momentum thresholds at 22 and 15 GeV for the leading and subleading lepton. Events with jets tagged as containing $b$-hadrons are rejected to suppress background contributions originating from top-quark production. Contributions from $W \rightarrow \tau\nu$ decays in which the $\tau$-leptons subsequently decay into electrons or muons are also included.

Selected events are classified according to the number of associated jets ($N_{jets}$). Exclusive $N_{jets} = 0$ and $N_{jets} = 1$ selections are enriched in signal events produced via ggF. To isolate regions with higher sensitivity, they are each further split into eight categories apiece, based on the flavor...
of the leading lepton (e or \(\mu\)), two bins of the invariant mass of the dilepton system \(m_{\ell\ell}\) and two bins of the transverse momentum of the subleading lepton \(p_T^{\ell_2}\). The distribution of the transverse mass of the dilepton plus \(E_T^{\text{miss}}\) system is used to separate the Higgs boson signal from background in each category. The \(N_{\text{jets}} \geq 2\) category is naturally sensitive to the VBF process. A central-jet veto is applied to suppress the multijet background and the contribution from ggF production. The output of a BDT exploiting the kinematic properties of the two leading jets and the two leptons is used to separate VBF Higgs boson production from background processes, including Higgs boson production via ggF.

### D. \(H \rightarrow \tau\tau\)

The \(H \rightarrow \tau\tau\) analysis [14] measures the Higgs boson production cross section in the VBF production process or in ggF production with large Higgs boson transverse momentum \(p_T^H\). Final states with both leptonic \((\tau\ell\ell)\) and hadronic \((\tau\text{had})\) decays of the \(\tau\)-lepton are considered. Selected lepton candidates are required to be of opposite charge, meet identification and isolation criteria and satisfy the \(p_T\) thresholds of the triggers used. Three mutually exclusive analysis channels, \(\tau_{\text{lep}}\tau_{\text{lep}}, \tau_{\text{lep}}\tau_{\text{had}},\) and \(\tau_{\text{had}}\tau_{\text{had}}\), are defined according to the number of selected electron, muon and hadron candidates. All channels require the presence of at least one jet with high transverse momentum.

To exploit signal-sensitive event topologies, candidate events are divided into three categories targeting the VBF process and two categories for high-\(p_T^H\) Higgs production. The VBF categories collect events with two jets with a large pseudorapidity separation and a high invariant mass \((m_{jj})\). The Higgs boson decay products are required to be in the central rapidity region. One VBF category is defined by requiring the transverse momentum of the \(\tau\tau\) system \(p_T^{\tau\tau}\) to be above 140 GeV, for \(\tau_{\text{had}}\tau_{\text{had}}\) events only. The two remaining VBF categories are defined for lower and higher values of \(m_{jj}\), with definitions that differ between the \(\tau_{\text{lep}}\tau_{\text{lep}}, \tau_{\text{lep}}\tau_{\text{had}},\) and \(\tau_{\text{had}}\tau_{\text{had}}\) channels. The high-\(p_T^H\) categories select events with large values of \(p_T^{\tau\tau}\), with contributions mainly from the ggF process. Events failing the VBF selection and with \(p_T^{\tau\tau} > 100\) GeV are selected. In order to improve the sensitivity of the analysis, two categories are defined for \(p_T^{\tau\tau} > 140\) GeV and \(p_T^{\tau\tau} \leq 140\) GeV, with additional selections on the angular separation between the \(\tau\)-leptons. The distribution of the invariant mass of the \(\tau\tau\) system is used to separate the Higgs boson signal from background in each category.

### E. \(H \rightarrow b\bar{b}\)

The \(H \rightarrow b\bar{b}\) decay channel is used to measure the production cross section in the \(VH\), VBF and \(t\bar{t}H\) production modes, the latter described in Sec. III G.

The search for \(H \rightarrow b\bar{b}\) in the \(VH\) production mode [15,16] considers final states containing at least two jets, of which exactly two must be tagged as containing \(b\)-hadrons. Either zero, one or two charged leptons are also required, exploring the associated production of a Higgs boson with a \(W\) or \(Z\) boson decaying leptonically as \(Z \rightarrow \nu\nu, W \rightarrow \ell\nu,\) or \(Z \rightarrow \ell\ell\). Contributions from \(W \rightarrow \tau\nu\) and \(Z \rightarrow \tau\tau\) decays in which the \(\tau\)-leptons subsequently decay into electrons or muons are also included.

To enhance the signal sensitivity, selected candidate events are classified according to the charged-lepton multiplicity, the vector-boson transverse momentum \(p_T^V\), and the jet multiplicity. For final states with zero or one lepton, \(p_T^V > 150\) GeV is required. In two-lepton final states, two regions are considered, \(75\) GeV < \(p_T^V < 150\) GeV and \(p_T^V > 150\) GeV. The \(p_T^V\) thresholds are chosen to select regions with strong experimental sensitivity, and match the STXS definitions described in Sec. VI A. Each of these regions is finally separated into a category with exactly two reconstructed jets and another with three or more. In the zero- and one-lepton channel, events with four or more jets are rejected. Topological and kinematic selection criteria are applied within each of the resulting categories. BDTs incorporating the event kinematics and topology, in addition to the dijet invariant mass, are employed in each lepton channel and analysis region to separate the signal process from the sum of the expected background processes.

The \(H \rightarrow b\bar{b}\) mode is also used to measure the VBF production process [17]. Three orthogonal selections are employed, targeting two all-hadronic channels and a photon-associated channel. Each selection requires the presence of at least two jets tagged as containing \(b\)-hadrons in the central pseudorapidity region \(|\eta| < 2.5\) as well as at least two additional jets used to identify the VBF topology.

The first of these two all-hadronic selections requires the \(b\)-tagged jets to have transverse momenta larger than 95 GeV and 70 GeV, while one of the additional jets is required to be in the forward region \(3.2 < |\eta| < 4.4\) and have a transverse momentum larger than 60 GeV and another must satisfy \(p_T > 20\) GeV and \(|\eta| < 4.4\). The transverse momentum \(p_T^{\gamma}\) of the system composed of the two \(b\)-tagged jets must be larger than 160 GeV.

The second all-hadronic selection with four central jets is defined by the presence of two jets with \(|\eta| < 2.8\) in addition to the \(b\)-tagged jets with \(|\eta| < 2.5\). All selected jets must pass a common threshold requirement of 55 GeV on their transverse momenta. The \(p_T\) of the \(b\bar{b}\)-system is required to be larger than 150 GeV. Events containing at least one forward jet satisfying the selection criteria of the first all-hadronic channel are removed.

A VBF + \(\gamma\) selection is defined by the presence of a photon with transverse momentum \(p_T > 30\) GeV and \(|\eta| < 2.37\), excluding the region \(1.37 < |\eta| < 1.52\), which suppresses the dominant background from nonresonant \(b\bar{b}jj\) production. Events must have at least four jets, all satisfying \(p_T > 40\) GeV and \(|\eta| < 4.4\), with at least two jets in \(|\eta| < 2.5\) passing the \(b\)-tag requirements.
The invariant mass of the VBF jets is required to be higher than 800 GeV, and $p_{T}^{bb} > 80$ GeV.

In all three selections a BDT built from variables describing jet and photon kinematics is used to enhance the sensitivity, and the distribution of the invariant mass $m_{bb}$ of the two $b$-tagged jets is used to separate the Higgs boson signal from background.

The VBF, $H \rightarrow b\bar{b}$ channels are included in all the measurements except for those presented in Sec. VI.

### F. $H \rightarrow \mu\mu$

The $H \rightarrow \mu\mu$ search uses a similar technique to the $H \rightarrow \gamma\gamma$ analysis, requiring a pair of opposite-charge muons. The analysis closely follows the $H \rightarrow \mu\mu$ search described in Ref. [20], which used a smaller dataset collected in the years 2015 and 2016 only.

Events are classified into eight categories. The output of a BDT exploiting the kinematic properties of the two leading jets and the two muons is used to define two categories targeting the VBF process. In order to enhance the sensitivity of the analysis, the remaining events are classified into three ranges of the transverse momentum $p_{T}^{\mu\mu}$ of the dimuon system ($p_{T}^{\mu\mu} < 15$ GeV, $15$ GeV $\leq p_{T}^{\mu\mu} < 50$ GeV and $p_{T}^{\mu\mu} \geq 50$ GeV) and two ranges of the muon pseudorapidities $\eta^{\mu}$ (both muons within $|\eta^{\mu}| \leq 1$, or at least one muon outside this range), for a total of six categories. The distribution of the invariant mass $m_{\mu\mu}$ of the two muons is used to separate signal from background in each category.

The analysis is not sensitive at the level of the Higgs boson signal expected in the SM, and is only included in the results presented in Section VII D.

### G. $t\bar{t}H$, $H \rightarrow b\bar{b}$ and $t\bar{t}H$ multilepton analyses

Searches for the associated production of the Higgs boson with a $t\bar{t}$ pair have been performed using Higgs boson decays into $b\bar{b}$ [19] and in multilepton final states, targeting Higgs boson decays into $WW$, $ZZ$ and $\tau\tau$. These analyses complement the selections sensitive to $t\bar{t}H$ production defined in the analyses of the $H \rightarrow \gamma\gamma$ and $H \rightarrow ZZ \rightarrow 4\ell$ decay channels, described in Secs. III A and III B.

The search for $t\bar{t}H$ production with $H \rightarrow b\bar{b}$ employs two selections, optimized for single-lepton and dilepton final states of $t\bar{t}$ decays. In the single-lepton channel, events are required to have one isolated electron or muon and at least five jets, of which at least two must be identified as containing $b$-hadrons. In the dilepton channel, events are required to have two opposite-charge leptons and at least three jets, of which at least two must be identified as containing $b$-hadrons. Candidate events are classified into 11 (7) orthogonal categories in the single-lepton (dilepton) channel, according to the jet multiplicity and the values of the $b$-tagging discriminant for the jets. In the single-lepton channel, an additional category, referred to as boosted, is designed to select events with large transverse momenta for the Higgs candidate ($p_{T}^{H} > 200$ GeV) and one of the top-quark candidates ($p_{T}^{T} > 250$ GeV). In each region, a BDT exploiting kinematic information of the events is employed to separate $t\bar{t}H$ production from background processes.

The $t\bar{t}H$ search with Higgs boson decays into $WW$, $ZZ$ and $\tau\tau$ exploits several multilepton signatures resulting from leptonic decays of vector bosons and/or the presence of $tH$ candidates. Seven final states, categorized by the number and flavor of reconstructed charged-lepton candidates, are examined. They are: one lepton with two $tH$ candidates, two same-charge leptons with zero or one $tH$ candidate, three leptons with zero or one $tH$ candidate, and four leptons, excluding events $H \rightarrow ZZ \rightarrow 4\ell$ decays. Events in all channels are required to have at least two jets, at least one of which must be $b$-tagged. Additional requirements are employed for each final state. Multivariate analysis techniques exploiting the kinematic properties and topologies of the selected events are applied in most channels to improve the discrimination between the signal and the background.

### H. Searches for invisible Higgs boson decays

Searches for decays of the Higgs boson into invisible final states select events with large missing transverse momentum; backgrounds are suppressed by requiring in addition either jets with a VBF topology [21], an associated $Z$ boson decaying into charged leptons [22] or an associated $W$ or $Z$ boson decaying into hadronic final states [23].

Production in the VBF topology is identified by requiring two jets with a pseudorapidity difference $|\Delta\eta_{jj}| > 4.8$ and invariant mass $m_{jj} > 1$ TeV. The missing transverse momentum is required to be larger than 180 GeV. Events with isolated lepton candidates or additional jets are rejected. Three signal regions are defined for $1 < m_{jj} < 1.5$ TeV, $1.5 < m_{jj} < 2$ TeV and $m_{jj} > 2$ TeV.

Production in association with a leptonically decaying $Z$ boson is identified by requiring the presence of a pair of isolated electrons or muons with an invariant mass close to $m_{Z}$. The missing transverse momentum is required to be larger than 90 GeV. It must also be larger than 60% of the scalar sum of the transverse momenta of the identified leptons and jets, and must be oriented back-to-back with the dilepton system in the transverse plane.

Two event topologies are considered in order to identify production in association with a hadronically decaying $W$ and $Z$ boson. The resolved topology is defined by the presence of two jets compatible with originating from the hadronic decay of a $W$ or $Z$ boson, reconstructed using the anti-$k_{T}$ algorithm [133] with a radius parameter of 0.4. The merged topology identifies $W$ or $Z$ bosons with large transverse momentum through the presence of a single jet, reconstructed using the anti-$k_{T}$ algorithm with a radius parameter of 1. The missing transverse momentum is
required to be larger than 150 GeV and 250 GeV for the resolved and boosted topologies respectively. In both cases, events are categorized according to the multiplicity of jets tagged as containing $b$-quarks. A separate category is also defined for events in which the mass of the jet system, defined as the dijet mass in the resolved topology and the mass of the large-radius jet in the merged topology, is compatible with a hadronic $W$ or $Z$ decay.

The statistical combination of these analyses [24] yields an observed (expected) upper limit on the branching fraction for Higgs boson decays into invisible final states of $B_{\text{inv}} < 0.38 \pm 0.21$ at 95% confidence level. In this paper, these analyses are only included in the coupling measurements presented in Secs. VIIC and VIIE.

I. Off-shell Higgs boson production

Measurements of the $H^* \rightarrow ZZ$ final state in the mass range above the $2m_Z$ threshold (off-shell region) provide an opportunity to measure the off-shell coupling strength of the observed Higgs boson, as discussed in Refs. [134–137]. The $ZZ \rightarrow 4\ell$ and $ZZ \rightarrow 2\ell 2\nu$ decay channels, detailed in Ref. [25], are used in these measurements.

Assuming that the coupling modifiers are identical for on-shell and off-shell production, the total width of the Higgs boson can be constrained from a combination with the on-shell measurements. It is also assumed that the coupling modifiers are independent of the momentum transfer of the Higgs boson production mechanism considered in the analysis, and that any new physics which modifies the off-shell signal strength and the off-shell couplings does not modify the relative phase of the interfering signal and background processes. Further, it is assumed that there are neither sizable kinematic modifications to the off-shell signal nor new sizable signals in the search region of this analysis unrelated to an enhanced off-shell signal strength [138,139].

The analysis in the $ZZ \rightarrow 4\ell$ final state closely follows the Higgs boson measurements in the same final state, described in Sec. IIIB, with the same event reconstruction, trigger and event selections and background estimation methods. The off-peak region is defined to cover the range $220 \text{ GeV} < m_{4\ell} < 2000 \text{ GeV}$. The distribution of a matrix-element-based discriminant constructed to enhance the $gg \rightarrow H^* \rightarrow ZZ$ is used to separate the Higgs boson signal from background processes.

The analysis in the $ZZ \rightarrow 2\ell 2\nu$ channel is similar to the one designed to search for heavy $ZZ$ resonances [140] with the same object definitions. The analysis is performed inclusively in the number of final-state jets and kinematic selections are optimized accordingly. Sensitivity to the off-shell Higgs boson signal is obtained through the distribution of the transverse mass $m_{T}^{ZZ}$ reconstructed from the momentum of the dilepton system and the missing transverse momentum [25], within the range $250 \text{ GeV} < m_{T}^{ZZ} < 2000 \text{ GeV}$. These off-shell analyses are only included in the coupling measurements presented in Sec. VII E.

IV. STATISTICAL MODEL

The statistical methods used in this paper follow those of Ref. [9]. The results of the combination are obtained from a likelihood function defined as the product of the likelihoods of each input analysis. These are themselves products of likelihoods computed in mutually exclusive regions selected in the analysis, referred to as analysis categories.

The number of signal events in each analysis category $k$ is expressed as

$$n_{k}^{\text{signal}} = \mathcal{L}_{k} \sum_{i} \sum_{f} (\sigma \times B)_{i f} (A \times e)_{i f, k}$$

where the sum runs over production modes $i$ ($i = ggF, VBF, WH, ZH, t\bar{t}H, \ldots$) and decay final states $f$ ($f = \gamma\gamma, ZZ', WW', \tau\tau, bb, \mu\mu$), $\mathcal{L}_{k}$ is the integrated luminosity of the dataset used in category $k$, and $(A \times e)_{i f, k}$ is the acceptance times efficiency factor in category $k$ for production mode $i$ and final state $f$. The cross section times branching fraction $(\sigma \times B)_{i f}$ for each relevant pair $(i, f)$ are the parameters of interest of the model. The measurements presented in this paper are obtained from fits in which these products are free parameters (Sec. V C), or in which they are re-expressed in terms of smaller sets of parameters: of a single signal-strength parameter $\mu$ (Sec. VA), of the cross sections $\sigma_i$ in each of the main production modes (Sec. VB), of ratios of cross sections and branching fractions (Secs. VD and VIB) or of coupling modifiers (Sec. VII). Additional parameters, referred to as nuisance parameters, are used to describe systematic uncertainties and background quantities that are constrained by sidebands or control regions in data.

Systematic uncertainties that affect multiple analyses are modeled with common nuisance parameters to propagate the effects of these uncertainties coherently to all measurements. The assessment of the associated uncertainties varies between data samples, reconstruction algorithms and software releases, leading to differences particularly between analyses performed using the 2017 dataset and those using 2015 and 2016 data only. Between these two sets of analyses, components of systematic uncertainties in the luminosity, the jet energy scale, the electron/photon resolution and energy scale, and in the electron reconstruction and identification efficiencies are also treated as correlated. Uncertainties due to the limited number of simulated events used to estimate expected signal and background yields are included using the simplified version of the Beeston–Barlow technique [141] implemented in the HISTFACTORY tool [142]. They are counted among the systematic uncertainties.
Theory uncertainties in the signal, such as missing higher-order QCD corrections and PDF-induced uncertainties, affect the expected signal yields of each production and decay process, as well as the signal acceptance in each category. These uncertainties are modeled by a common set of nuisance parameters in most channels. For the signal-strength (Sec. VA) and coupling modifier (Sec. VII) results and constraints on new phenomena (Sec. VIII), which rely on the comparison of measured and SM-expected yields, both the acceptance and signal yield uncertainties are included. For the cross section and branching fraction results of Secs. VB and VI, only acceptance uncertainties are considered. The effects of correlations between Higgs boson branching fractions are modeled using the correlation model specified in Ref. [35]. Uncertainties due to dependencies on SM parameter values and missing higher-order effects are applied to the partial decay widths and propagated to the branching fractions. The uncertainties due to modeling of background processes are typically treated as uncorrelated between analyses.

The measurement of the parameters of interest is carried out using a statistical test based on the profile likelihood ratio [143],

\[
\Lambda(\alpha) = \frac{L(\alpha, \hat{\theta}(\alpha))}{L(\hat{\alpha}, \hat{\theta})},
\]

where \(\alpha\) and \(\theta\) are respectively the parameters of interest and the nuisance parameters. In the numerator, the nuisance parameters are set to their profiled values \(\hat{\theta}(\alpha)\), which maximize the likelihood function for fixed values of the parameters of interest \(\alpha\). In the denominator, both the parameters of interest and the nuisance parameters are set to the values \(\hat{\alpha}\) and \(\hat{\theta}\) respectively which jointly maximize the likelihood.

In the asymptotic regime, in which the likelihood is approximately Gaussian, the value of \(-2 \ln \Lambda(\alpha)\) follows a \(\chi^2\) distribution with a number of degrees of freedom (d.o.f.) \(n\) equal to the dimensionality of the vector \(\alpha\) [143]. This property is assumed to hold for all the results presented in the following sections. Confidence intervals for a confidence level (CL) \(1 - p\) are then defined as the regions with values of \(-2 \ln \Lambda(\alpha)\) below a threshold \(F^{-1}_{\chi^2}(1 - p)\), where \(F^{-1}_{\chi^2}\) is the quantile function of the \(\chi^2\) distribution with \(n\) d.o.f.

The \(\text{CL}_s\) prescription [144] is applied when setting an upper limit on a single parameter directly related to measured event rates, for instance a production cross section. When setting limits in more than one dimension, the \(\text{CL}_s\) procedure is not applied.

For relevant parameters of interest, a physical bound on the parameter values is included in the statistical interpretation. For example, branching fraction parameters cannot conceptually be smaller than zero. The 95\% confidence interval quoted for such parameters is then based on the profile likelihood ratio restricted to the allowed region of parameter space, using the \(t_c\) test statistic of Ref. [143]. The confidence interval is defined by the standard \(\chi^2\) cutoff, which leads to some overcoverage near the boundaries.

Uncertainties in the measurement parameters are in some cases broken down into separate components for theory uncertainties affecting the background processes, theory uncertainties affecting the Higgs boson signal production, experimental uncertainties including Monte Carlo (MC) statistical uncertainties, and statistical uncertainties. Each component is derived by fixing the associated nuisance parameters to their best-fit values \(\hat{\theta}\) in both the numerator and denominator of \(\Lambda\), and computing again the uncertainty in the measurement parameters. This is done for each component in turn, following the order in which they are listed above. The uncertainty obtained at each step is then subtracted in quadrature from the uncertainty obtained in the previous step (in the first step, from the total uncertainty) to obtain the corresponding uncertainty component. The statistical uncertainty component is obtained in the last step, with all nuisance parameters fixed except for the ones that are only constrained by data, such as parameters used to describe data-driven background estimates.

For the systematic uncertainties reported in the detailed breakdowns shown for instance in Table III, a simpler procedure is used: in each case the corresponding nuisance parameters are fixed to their best-fit values, while other nuisance parameters are left free, and the resulting uncertainty is subtracted in quadrature from the total uncertainty.

The probability of compatibility with the Standard Model is quantified using the test statistic \(\lambda_{SM} = -2 \ln \Lambda(\alpha = \alpha_{SM})\), where \(\alpha_{SM}\) are the Standard Model values of the parameters of interest. A \(p\)-value \(^3\) \(p_{SM}\) for the probability of compatibility is computed in the asymptotic approximation as \(p_{SM} = 1 - F_{\chi^2}^{-1}(\lambda_{SM})\), with \(n\) equal to the number of free parameters of interest. For the cross section and branching fraction measurements reported in this paper, this definition does not account for the uncertainties in the SM values used as reference and may therefore lead to an underestimate of the probability of compatibility with the SM.

Results for expected significances and limits are obtained using the Asimov dataset technique [143].

The correlation coefficients presented in this paper are constructed to be symmetric around the observed best-fit values of the parameters of interest using the second derivatives of the negative log-likelihood ratio. Hence, the correlation matrices shown are not fully representative of the observed asymmetric uncertainties in the measurements. While the reported information is sufficient to reinterpret the measurements in terms of other

---

\(^3\)The \(p\)-value is defined as the probability to obtain a value of the test statistic that is at least as high as the observed value under the hypothesis that is being tested.
parameterizations of the parameters of interest, this provides only an approximation to the information contained in the full likelihood function. For this reason, results for a number of commonly used parameterizations are also provided in Secs. V–VII.

V. COMBINED MEASUREMENTS OF SIGNAL STRENGTH, PRODUCTION CROSS SECTIONS, AND BRANCHING RATIOS

A. Global signal strength

The global signal strength $\mu$ is determined following the procedures used for the measurements performed at $\sqrt{s} = 7$ and 8 TeV [9]. For a specific production mode $i$ and decay final state $f$, the signal yield is expressed in terms of a single modifier $\mu_{if}$, as the production cross section $\sigma_i$ and the branching fraction $B_f$ cannot be separately measured without further assumptions. The modifiers are defined as the ratios of the measured Higgs boson yields and their SM expectations, denoted by the superscript “SM”,

$$\mu_{if} = \frac{\sigma_i}{\sigma_i^{SM}} \times \frac{B_f}{B_f^{SM}}.$$  \hspace{1cm} (2)

The SM expectation by definition corresponds to $\mu_{if} = 1$. The uncertainties in the SM predictions are included as nuisance parameters in the measurement of the signal strength modifiers, following the methodology introduced in Sec. IV, where the procedures to decompose the uncertainties are also described.

In the model used in this section, all the $\mu_{if}$ are set to a global signal strength $\mu$, describing a common scaling of the expected Higgs boson yields in all categories. Its combined measurement is

$$\mu = 1.11^{+0.09}_{-0.08} = 1.11 \pm 0.05 \text{(stat)} \pm 0.05 \text{(exp)} \pm 0.04 \text{(sig th)} \pm 0.03 \text{(bkg th)}$$

where the total uncertainty is decomposed into components for statistical uncertainties, experimental systematic uncertainties, and theory uncertainties in signal and background modeling. The signal theory component includes uncertainties due to missing higher-order perturbative QCD and electroweak corrections in the MC simulation, uncertainties in PDF and $\alpha_s$ values, the treatment of the underlying event, the matching between the hard-scattering process and the parton shower, choice of hadronization models, and branching fraction uncertainties. The measurement is consistent with the SM prediction with a $p$-value of $p_{SM} = 18\%$, computed using the procedure defined in Sec. IV with one d.o.f. The value of $-2 \ln \Lambda(\mu)$ as a function of $\mu$ is shown in Fig. 1, for the full likelihood and the versions with sets of nuisance parameters fixed to their best-fit values to obtain the components of the uncertainty.

Table III shows a summary of the leading uncertainties in the combined measurement of the global signal strength. The dominant uncertainties arise from the theory modeling of the signal and background processes in simulation. Further important uncertainties relate to the luminosity measurement; the selection efficiencies, energy scale and energy resolution of electrons and photons; the estimate of lepton yields from heavy-flavor decays, photon conversions or misidentified hadronic jets (classified as background modeling in the table); the jet energy scale and resolution, and the identification of heavy-flavor jets.

B. Production cross sections

Higgs boson production is studied in each of its main production modes. The production mechanisms considered are ggF, VBF, WH, ZH (including $gg \rightarrow ZH$), and the combination of $t\bar{t}H$ and $tH$ ($t\bar{t}H + tH$). In cases where several processes are combined, the combination assumes the relative fractions of each component to be as in the SM, with theory uncertainties assigned. The small contribution from $b\bar{b}H$ is grouped with ggF. Cross sections are reported in the region $|y_H| < 2.5$ of the Higgs boson rapidity $y_H$. Results are obtained in a simultaneous fit to the data, with the cross sections of each production mechanism as parameters of interest. Higgs boson decay branching
TABLE III. Summary of the relative uncertainties $\Delta \mu / \mu$ affecting the measurement of the combined global signal strength $\mu$. "Other" refers to the combined effect of the sources of experimental systematic uncertainty not explicitly listed in the table. The sum in quadrature of systematic uncertainties from individual sources differs from the uncertainty evaluated for the corresponding group in general, due to the presence of small correlations between nuisance parameters describing the different sources and other effects which are not taken into account in the procedure described in Sec. IV.

fractions are set to their SM values, within the uncertainties specified in Ref. [35].

The results are shown in Fig. 2 and Table IV. The leading sources of uncertainty in the production cross section measurements are summarized in Table V, with uncertainties computed as described in Sec. IV. The measured $t\bar{t}H + tH$ production cross section differs from the $t\bar{t}H$ cross section reported in Ref. [12], even after accounting for the difference between the $|y_H| < 2.5$ region used in this paper and the inclusive phase space considered in Ref. [12]. This is due in part to the inclusion of $tH$, which in Ref. [12] is fixed to the SM expectation and not included in the reported $t\bar{t}H$ cross section, as well as to better control of systematic effects, especially those related to photon energy scale and resolution, due to the $H \rightarrow \gamma\gamma$ categories targeting other processes which are included in this combination, as described in Sec. III A. The correlations between the measured cross sections, shown in Figure 3, are significantly reduced relative to previous analyses [9,145].

A modest correlation of $-15\%$ between the ggF and VBF processes remains, however, because of contributions from ggF production in the VBF-enriched selections. The probability of compatibility between the measurement and the SM prediction corresponds to a $p$-value of $p_{SM} = 76\%$, computed using the procedure outlined in Sec. IV with five d.o.f.

Figure 4 shows the observed likelihood contours in the plane of $\sigma_{ggF}$ versus $\sigma_{VBF}$ from individual channels and the combined fit, together with the SM prediction. The cross sections for the other production modes are profiled. Significances above $5\sigma$ are observed for the combined measurements of the ggF, VBF, $VH$ and $t\bar{t}H + tH$ production processes. For the VBF process, the observed (expected) significance is $6.5\sigma$ ($5.3\sigma$). For the WH and ZH modes, these are respectively $3.5\sigma$ ($2.7\sigma$) and $3.6\sigma$ ($3.6\sigma$). Combining $WH$ and $ZH$ production into a single VH process, with the ratio of $WH$ to $ZH$ production set to its SM value leads to an observed (expected) significance for

FIG. 2. Cross sections for ggF, VBF, $WH$, $ZH$ and $t\bar{t}H + tH$ normalized to their SM predictions, measured with the assumption of SM branching fractions. The black error bars, blue boxes and yellow boxes show the total, systematic, and statistical uncertainties in the measurements, respectively. The gray bands indicate the theory uncertainties in the cross section predictions.
TABLE IV. Best-fit values and uncertainties for the production cross sections of the Higgs boson, assuming SM values for its decay branching fractions. The total uncertainties are decomposed into components for data statistics (Stat.), experimental systematic uncertainties (Exp.), and theory uncertainties in the modeling of the signal (Sig. th.) and background (Bkg. th.) processes. SM predictions are shown for the cross section of each production process. They are obtained from the inclusive cross sections and associated uncertainties reported in Sec. II. The observed (obs.) and expected (exp.) significances of the observed signals relative to the no-signal hypothesis are also shown in Ref. [35], multiplied by an acceptance factor for the region $|y_H| < 2.5$ computed using the Higgs boson simulation samples described in Sec. IV.

this process of $5.3\sigma (4.7\sigma)$. For the combination of $tH$ and $tH$ production, the observed (expected) significance is $5.8\sigma (5.4\sigma)$.

C. Products of production cross sections and branching fractions

A description of both the production and decay mechanisms of the Higgs boson is obtained by considering the products $(\sigma \times B)_i^f$ of the cross section in production process $i$ and branching fraction to final state $f$. The production processes are defined as in Sec. VB except for the fact that the $WH$ and $ZH$ processes, which cannot be reliably determined in all decay channels except $H \rightarrow b\bar{b}$, are considered together as a single $VH$ process, with the ratio of $WH$ to $ZH$ cross sections fixed to its SM value within uncertainties. The decay modes considered are $H \rightarrow WW$, $H \rightarrow ZZ$, $H \rightarrow WW^*$, $H \rightarrow \tau\tau$ and $H \rightarrow b\bar{b}$. There are in total 20 such independent products, but the analyses included in the combination provide little sensitivity to ggF production in the $H \rightarrow b\bar{b}$ decay mode, and to VH production in the $H \rightarrow WW^*$ and $H \rightarrow \tau\tau$ decay modes. The corresponding products are therefore fixed to their SM

TABLE V. Summary of the uncertainties affecting the production cross section measurements. “Other” refers to the combined effect of the sources of experimental systematic uncertainty not explicitly listed in the table. The sum in quadrature of systematic uncertainties from individual sources differs from the uncertainty evaluated for the corresponding group in general, due to the presence of small correlations between nuisance parameters describing the different sources and other effects which are not taken into account in the procedure described in Sec. IV.

values within uncertainties. For the same reason, in \(t\bar{t}H\) production the \(H \rightarrow ZZ^*\) decay mode is considered together with \(H \rightarrow WW^*\) as a single \(H \rightarrow VV^*\) process, with the ratio of \(H \rightarrow ZZ^*\) to \(H \rightarrow WW^*\) fixed to its SM value. The results are obtained from a simultaneous fit of all input analyses, with the 16 independent \((\sigma \times B)\) products defined above as parameters of interest. They are shown in Figure 5 and Table VI. The correlation matrix of the measurements is shown in Figure 6. The largest terms in absolute value are between the \(t\bar{t}H\) processes, and between the ggF, \(H \rightarrow \tau\tau\) and VBF, \(H \rightarrow \tau\tau\) processes. In both cases, this is due to cross-contamination between these processes in the analyses providing the most sensitive measurements. The probability of compatibility between the measurement and the SM prediction corresponds to a p-value of \(p_{SM} = 71\%\), computed using the procedure outlined in Sec. IV with 16 d.o.f.

D. Ratios of cross sections and branching fractions

The products \((\sigma \times B)_{if}\) described in Sec. V C can be expressed as

\[
(\sigma \times B)_{if} = \frac{\sigma_{VBF}}{\sigma_{ggF}} \cdot \frac{B_{if}}{B_{ZZ}}.
\]
TABLE VI. Best-fit values and uncertainties for the production cross sections times branching fractions of the Higgs boson, for the combinations in which sufficient sensitivity is provided by the input analyses. Combinations not shown in the table are fixed to their SM values within uncertainties. For $t\bar{t}H + tH$ production, $H \to VV^*$ refers to the combination of $H \to WW^*$ and $H \to ZZ^*$, with a relative weight fixed by their respective SM branching fractions. The total uncertainties are decomposed into components for data statistics (Stat.), experimental systematic uncertainties (Exp.), and theory uncertainties in the modeling of the signal (Sig. th.) and background (Bkg. th.) processes. SM predictions [35] are shown for each process.

The gray bands show the theory uncertainties in the predictions.
VI. COMBINED MEASUREMENTS OF SIMPLIFIED TEMPLATE CROSS SECTIONS

A. Simplified template cross section framework

Simplified template cross sections \cite{35,36} are defined through a partition of the phase space of the SM Higgs production process into a set of nonoverlapping regions. These regions are defined in terms of the kinematics of the Higgs boson and, when they are present, of associated jets and $W$ and $Z$ bosons, independently of the Higgs boson decay process. They are chosen according to three criteria: sensitivity to deviations from the SM expectation, avoidance of large theory uncertainties in the corresponding SM predictions, and to approximately match experimental selections so as to minimize model-dependent extrapolations. Analysis selections do not, however, necessarily correspond exactly to the STXS regions.

All regions are defined for a Higgs boson rapidity $y_H$ satisfying $|y_H| < 2.5$, corresponding approximately to the region of experimental sensitivity. Jets are reconstructed from all stable particles with a lifetime greater than 10 ps, excluding the decay products of the Higgs boson and leptons from $W$ and $Z$ boson decays, using the anti-$k_t$ algorithm with a jet radius parameter $R = 0.4$, and must have a transverse momentum $p_T^{\text{jet}} > 30$ GeV.

The measurements presented in this paper are based on the Stage 1 splitting of the STXS framework \cite{35}. Higgs boson production is first classified according to the nature of the initial state and of associated particles, the latter including the decay products of $W$ and $Z$ bosons if they are present. These categories are, by order of decreasing selection priority: $t\bar{t}H$ and $tH$ processes; $qq \to Hqq$ processes, with contributions from both VBF production and quark-initiated $VH$ production with a hadronic decay of the gauge boson; $gg \toZH$ with $Z \to q\bar{q}$; $VH$ production with a leptonic decay of the vector boson ($V(\text{lep})H$), including $gg \toZH$ production; and finally the gluon–gluon fusion process. The last is considered together with $gg \toZH$, $Z \to q\bar{q}$ production, as a single $gg \to H$ process. The $b\bar{b}H$ production mode is modeled as a 1% \cite{35} increase of the $gg \to H$ yield in each STXS bin, since the acceptances for both processes are similar for all input analyses \cite{35}. The $t\bar{t}H$ and $tH$ processes are also combined in a single $t\bar{t}H + tH$ category, assuming the relative fraction of each component to be as in the SM, within uncertainties.

The analyses included in this paper provide only limited sensitivity to the cross section in some bins of the Stage 1 scheme, mainly due to limited data statistics in some regions. In other cases, they only provide sensitivity to a combination of bins, leading to strongly correlated measurements. To mitigate these effects, the results are presented in terms of a reduced splitting, with the measurement bins defined as merged groups of Stage 1 bins (and in the case of $V(\text{lep})H$ with an additional splitting not

![Diagram](image.png)

FIG. 8. Definition of the STXS measurement regions used in this paper. For each Higgs boson production process, the regions are defined starting from the top of the corresponding schematic, with regions nearer the top taking precedence if the selections overlap. The $b\bar{b}H$ production mode is considered as part of $gg \to H$. 

G. AAD et al. PHYS. REV. D 101, 012002 (2020)
These measurement bins are defined as follows for each measurement region and of the ratios of branching fractions $B_{f}/B_{ZZ}$, normalized to the SM predictions for the various parameters. The parameters directly extracted from the fit are the products $(\sigma_{f}\times B_{ZZ})$ and the ratios $B_{f}/B_{ZZ}$. The black error bar shows the total uncertainty in each measurement.

FIG. 9. Best-fit values and uncertainties for the cross sections in each measurement region and of the ratios of branching fractions $B_{f}/B_{ZZ}$, normalized to the SM predictions for the various parameters. The parameters directly extracted from the fit are the products $(\sigma_{f}\times B_{ZZ})$ and the ratios $B_{f}/B_{ZZ}$. The black error bar shows the total uncertainty in each measurement.

present in the original Stage 1 scheme, as described below). These measurement bins are defined as follows for each process:

(i) $gg\rightarrow H$ is separated into regions defined by the jet multiplicity and the Higgs boson transverse momentum $p_{T}^{H}$. A region is defined for events with one or more jets and $p_{T}^{H} \geq 200$ GeV, providing sensitivity to deviations from the SM at high momentum transfer. The remaining events are separated into classes with 0, 1 and $\geq 2$ jets in the final state. The one-jet category is further split in bins of $p_{T}^{H}$, probing perturbative QCD predictions and providing sensitivity to deviations from the SM. Three bins are defined with $p_{T}^{H} < 60$ GeV, 60 GeV $\leq p_{T}^{H} < 120$ GeV and 120 GeV $\leq p_{T}^{H} < 200$ GeV.

(ii) $qq\rightarrow H qq$ is separated into three regions. The first selects events in which the transverse momentum of the leading jet $p_{T}^{1}$ is $\geq 200$ GeV. A second region, denoted by VH topo, is defined by $p_{T}^{1} < 200$ GeV and the presence of two jets with an invariant mass $m_{jj}$ in the range $60 \leq m_{jj} < 120$ GeV, selecting events originating from VH production in particular. The remaining events are grouped into a third bin, denoted by VBF topo+Rest, which includes mainly the VBF-topology region (VBF topo) defined by the presence of two jets with $m_{jj} \geq 400$ GeV and a pseudorapidity difference $|\Delta\eta_{jj}| \geq 2.8$, as well as events that fall in none of the above selections (Rest). The measurement sensitivity for the corresponding cross section is provided mainly by the VBF-topology region, within which the cross section is measured precisely by the analyses targeting VBF production.

(iii) $V(\text{lep})H$ is split into the two processes $qq\rightarrow WH$ and $pp\rightarrow ZH$, the latter including both quark-initiated and gluon-initiated production. These regions are further split according to $p_{T}^{V}$, the transverse momentum of the $W$ or $Z$ boson. For the $qq\rightarrow WH$ process two bins are defined for $p_{T}^{V} < 250$ GeV and $p_{T}^{V} \geq 250$ GeV, while for $pp\rightarrow ZH$ three bins are
defined for \( p_T^V < 150 \text{ GeV}, \) 150 GeV \( \leq p_T^V < 250 \text{ GeV} \) and \( p_T^V \geq 250 \text{ GeV} \). This definition deviates from the one given in Ref. [35], where the \( q\bar{q} \rightarrow ZH \) and \( gg \rightarrow ZH \) processes are measured separately and no splitting is performed at \( p_T^V = 250 \text{ GeV} \) for \( gg \rightarrow ZH \), given the limited sensitivity of the current measurements to separating the \( q\bar{q} \rightarrow ZH \) and \( gg \rightarrow ZH \) processes.

The above merging scheme of Stage 1 bins is summarized in Figure 8.

Sensitivity to the 0-jet and 1-jet, \( p_T^H < 60 \text{ GeV} \) regions of the \( gg \rightarrow H \) process is provided mainly by the \( H \rightarrow ZZ^* \rightarrow 4\ell, H \rightarrow \gamma\gamma \) and \( H \rightarrow WW^* \rightarrow e\nu\mu \nu \) analyses, with the leading contribution in each region coming from \( H \rightarrow WW^* \rightarrow e\nu\mu \nu \) and \( H \rightarrow \gamma\gamma \) respectively. For the 1-jet, 60 \( \leq p_T^H < 120 \text{ GeV} \) region, the main contributions to the sensitivity are from \( H \rightarrow ZZ^* \rightarrow 4\ell \) and \( H \rightarrow \gamma\gamma \), dominated by the latter. The \( H \rightarrow \gamma\gamma \) analysis also provides the largest sensitivity in the rest of the \( gg \rightarrow H \) regions as well as in the \( q\bar{q} \rightarrow Hq\bar{q} \) sector, apart from the \( p_T^V > 200 \text{ GeV} \) region for which \( H \rightarrow \tau\tau \) dominates the sensitivity. The \( VH, H \rightarrow b\bar{b} \) analysis provides the most sensitive measurements in the \( V(\text{lep})H \) regions. Finally, the \( H \rightarrow \gamma\gamma \) and \( t\bar{t}H \) multilepton analyses provide the leading contributions to the measurement of the \( t\bar{t}H + tH \) region.

The measured event yields are described by Eq. (1), with parameters of interest of the form \((\epsilon \times B)_{ij}^f\) denoting the cross section times branching fraction in STXS region \( i \) and decay channel \( f \). The acceptance factors \((\epsilon \times A)_{ij}^f\) for each analysis category \( k \) are determined from SM Higgs boson production processes, modeled using the samples described in Sec. II, and act as templates in the fits of the STXS cross sections to the data. The dependence on the theory assumptions is less than in the measurement of the total cross sections in each production mode, since the \((\epsilon \times A)_{ij}^f\) are computed over smaller regions. Assumptions about the kinematics within a given STXS region lead to some

**TABLE VIII.** Best-fit values and uncertainties for the cross sections in each measurement region, and of the ratios of branching fractions \( B_f/B_{ZZ} \). The total uncertainties are decomposed into components for data statistics (Stat.) and systematic uncertainties (Syst.). The SM predictions [35] are also shown for each quantity with their total uncertainties. The parameters directly extracted from the fit are the products \((\sigma_i \times B_{ZZ})\) and the ratios \(B_f/B_{ZZ} \); the former are shown divided by the SM value of \(B_{ZZ}\).

model-dependence, which can be reduced further by using a finer splitting of the phase space, as allowed by experimental precision. Results using a splitting finer than the one described in this section are presented in Appendix.

Theory uncertainties for the $gg \to H$ and $qq \to Hgg$ processes are defined as in Ref. [10], while those of the $V(\text{lep})H$ process follow the scheme described in Ref. [146]. For the measurement bins defined by merging several bins of the STXS Stage-1 framework, the $(c \times A)$ factors are determined assuming that the relative fractions of each Stage-1 bin are as in the SM, and SM uncertainties in these fractions are taken into account.

## B. Results

The fit parameters chosen for the combined STXS measurements are the cross sections for Higgs boson production in STXS region $i$ times the branching fraction for the $H \to ZZ^*$ decay, $(\sigma \times B)^{i,ZZ}$, and the ratios of branching fractions $B_f/B_{ZZ}$ for the other final states $f$. Similarly to the ratio model in Sec. VD, the cross sections times branching fractions for final states other than $ZZ^*$ are parametrized as

$$(\sigma \times B)_{ij} = (\sigma \times B)^{i,ZZ} \frac{B_f}{B_{ZZ}}.$$ 

The observed upper limits at 95% CL on the cross sections in the $qq \to Hqq$, $VH$ topo and $qq \to Hqq$, $p_T^V \geq 200$ GeV bins are found to be 1.45 pb and 0.59 pb, respectively, taking into account the physical bound on the parameter values as discussed in Sec. IV. The corresponding expected upper limits are 1.53 pb and 0.80 pb, respectively.

The correlations between the measured parameters are shown in Fig. 11. The largest anticorrelations are between $B_{tt}/B_{ZZ}$ and the cross section measurements in the $V(\text{lep})H$ region, since the $VH, H \to bb$ analysis is sensitive to products of these quantities; between the cross section measurement in the $gg \to H$ 0-jet region and both $B_{tt}/B_{ZZ}$ and $B_{WW}/B_{ZZ}$, since the $H \to \gamma\gamma$, $H \to ZZ^* \to 4\ell$ and $H \to WW^* \to ee\mu\nu$ decay channels provide the most precise measurements in this region; between $B_{tt}/B_{ZZ}$ and the cross section measurement in the $qq \to Hqq$, VBF topo $+\text{Rest}$ region, since there is a tension between the $H \to \gamma\gamma$ and $H \to ZZ^* \to 4\ell$ measurements in this region; between $B_{tt}/B_{ZZ}$ and the cross section measurement in the $p_T^H > 200$ GeV region, since the high-$p_T^H$ channels of the $H \to \tau\tau$ analysis are sensitive to their product; and between the cross section measurements in the $qq \to Hqq$, $p_T^V \geq 200$ GeV and $gg \to H$, $1$-jet, $120 \leq p_T^H \geq 200$ GeV regions on the one hand, and the $qq \to Hqq$, $p_T^V \geq 200$ GeV and $gg \to H$, 1-jet, $120 \leq p_T^H < 200$ GeV regions on the other hand, since in both cases there is cross contamination between these processes in the experimental selections.

### ATLAS

$\sqrt{s} = 13$ TeV, $36.1 - 79.8$ fb$^{-1}$

$m_H = 125.09$ GeV, $|y_H| < 2.5$

![FIG. 11. Correlation matrix for the measured values of the simplified template cross sections and ratios of branching fractions. The fit parameters are the products $(\sigma_i \times B_{ZZ})$ and the ratios $B_f/B_{ZZ}$.](image-url)
The largest positive correlations are between the \((W \to \ell\nu)H\) and \((Z \to \ell\ell)H\) measurement regions, related to their strong anticorrelation with \(B_{bb}/B_{ZZ}\); and between \(B_{\gamma\gamma}/B_{ZZ}\) and \(B_{WW}/B_{ZZ}\), due to their strong anticorrelation with the cross section measurement in the 0-jet region.

The results show good overall agreement with the SM predictions in a range of kinematic regions of Higgs boson production processes. The probability of compatibility between the measurement and the SM prediction corresponds to a \(p\)-value of \(p_{SM} = 89\%\), computed using the procedure outlined in Sec. IV with 19 d.o.f.

VII. INTERPRETATION OF RESULTS IN THE \(\kappa\) FRAMEWORK

When testing the Higgs boson coupling strengths, the production cross sections \(\sigma_i\), decay branching fractions \(B_f\) and the signal-strength parameters \(\mu_{if}\) defined in Eq. (2) cannot be treated independently, as each observed process involves at least two Higgs boson coupling strengths. Scenarios with a consistent treatment of coupling strengths in Higgs boson production and decay modes are presented in this section.

A. Framework for coupling-strength measurements

Coupling-strength modifiers \(\kappa\) are introduced to study modifications of the Higgs boson couplings related to BSM physics, within a framework [37] (\(\kappa\)-framework) based on the leading-order contributions to each production and decay process. Within the assumptions made in this framework, the Higgs boson production and decay can be factorized, such that the cross section times branching fraction of an individual channel \(\sigma(i \to H \to f)\) contributing to a measured signal yield is parametrized as

\[
\sigma_i \times B_f = \frac{\sigma_i(\kappa) \times \Gamma_f(\kappa)}{\Gamma_H} \, ,
\]

where \(\Gamma_H\) is the total width of the Higgs boson and \(\Gamma_f\) is the partial width for Higgs boson decay into the final state \(f\). For a given production process or decay mode \(j\), the corresponding coupling-strength modifier \(\kappa_j\) is defined by

\[
\kappa_j^2 = \frac{\sigma_j}{\sigma_j^{SM}} \quad \text{or} \quad \kappa_j^2 = \frac{\Gamma_f}{\Gamma_f^{SM}}.
\]

The SM expectation, denoted by the label “SM,” by definition corresponds to \(\kappa_j = 1\).

The total width of the Higgs boson is affected both by modifications of the \(\kappa_j\), and contributions from two additional classes of Higgs boson decays: invisible decays, which are identified through an \(E_T^{miss}\) signature in the analyses described in Sec. III H; and undetected decays, to which none of the analyses included in this combination are sensitive (the latter includes for instance Higgs boson decays into light quarks, or to BSM particles to which none of the input analyses provide appreciable sensitivity). In the SM, the branching fraction for decays into invisible final states is \(\sim 0.1\%\), from the \(H \to ZZ' \to 4\nu\) process. BSM contributions to this branching fraction and to the branching fraction to undetected final states are denoted by \(B_{inv}\) and \(B_{undet}\) respectively, with the SM corresponding to \(B_{inv} = B_{undet} = 0\). The Higgs boson total width is then expressed as

\[
\Gamma_H(\kappa, B_{inv}, B_{undet}) = \kappa_H^2(\kappa, B_{inv}, B_{undet}) \Gamma_H^{SM} + \sum_j B_j^{SM} \kappa_j^2
\]

Constraints on \(B_{inv}\) are provided by the analyses described in Sec. III H, but no direct constraints are included for \(B_{undet}\). Since its value scales all observed cross sections of on-shell Higgs boson production \(\sigma(i \to H \to f)\) through Eqs. (3) and (4), further assumptions about undetected decays must be included in order to interpret these measurements in terms of absolute coupling-strength scale factors \(\kappa_j\). The simplest assumption is that there are no undetected Higgs boson decays and the invisible branching fraction is as predicted by the SM. An alternative, weaker assumption, is to require \(\kappa_{W} \leq 1\) and \(\kappa_{Z} \leq 1\) [37]. A second alternative uses the assumption that the signal strength of off-shell Higgs boson production only depends on the coupling-strength scale factors and not on the total width \([134,135]\), \(\sigma^{off}(i \to H' \to f) \sim \kappa_j^{off} \times \kappa_j^{off}\). If the coupling strengths in off-shell Higgs boson production are furthermore assumed to be identical to those for on-shell Higgs boson production, \(\kappa_j^{off} = \kappa_j^{on}\), and under the assumptions given in Sec. III I, the Higgs boson total width can be determined from the ratio of off-shell to on-shell signal strengths \([25,147]\). These assumptions can also be extended to apply to \(B_{inv}\) as well as \(B_{undet}\) as an alternative to the measurements of Sec. III H.

An alternative approach is to rely on measurements of ratios of coupling-strength scale factors, which can be measured without assumptions about the Higgs boson total width, since the dependence on \(\Gamma_H\) of each coupling strength cancels in their ratios.

The current LHC data are insensitive to the coupling-strength modifiers \(\kappa_j\). Thus, in the following it is assumed that \(\kappa_j\) varies as \(\kappa_j\) and \(\kappa_j\) varies as \(\kappa_j\). Other coupling modifiers \(\kappa_{\mu}, \kappa_{\nu}, \kappa_{\nu}\) are irrelevant for the combination provided they are of order unity. The \(gg \to H\), \(H \to gg\), \(gg \to ZH\), \(H \to \gamma\gamma\) and \(H \to ZZ\) processes are loop-induced in the SM. The \(ggH\) vertex and the \(H \to \gamma\gamma\) process are treated either using effective scale factors \(\kappa_{\gamma}\) and \(\kappa_{\gamma}\), respectively, or expressed in terms of the more fundamental coupling-strength scale factors corresponding to the particles that contribute to the loop, including all interference effects. The \(gg \to ZH\) process is never described using an effective scale factor and always resolved in terms of modifications of the SM Higgs bosons couplings to the

\[012002-20\]
top quark and the Z boson. This assumption impacts the description of BSM effects in $gg \rightarrow ZH$, since these lead to modified production kinematics [148]. However, the effect of introducing an explicit dependence on the transverse momentum of the Z boson in the parameterization was found to have a negligible impact on the results at the current level of experimental precision. Similarly, the $H \rightarrow Z\gamma$ decay is always expressed in terms of the Higgs boson couplings to the W boson and the $t$-quark as no analysis targeting this decay mode is included in the combination. These relations are summarized in Table IX. All uncertainties in the best-fit values shown in the following take into account both the experimental and theoretical systematic uncertainties, following the procedures outlined in Sec. IV.

### B. Fermion and gauge boson couplings

The model studied in this section probes the universal coupling-strength scale factors $\kappa_V = \kappa_W = \kappa_Z$ for all vector bosons and $\kappa_F = \kappa_t = \kappa_b = \kappa_{\tau} = \kappa_{\mu}$ for all fermions.

The effective couplings corresponding to the $ggH$ and $H \rightarrow \gamma\gamma$ vertex loops are resolved in terms of the fundamental SM couplings. It is assumed that there are no invisible or undetected Higgs boson decays, i.e., $B_{\text{inv}} = B_{\text{undet}} = 0$. Only the relative sign between $\kappa_V$ and $\kappa_F$ is physical. As a negative relative sign has been excluded [9], $\kappa_V \geq 0$ and $\kappa_F \geq 0$ are assumed. These definitions can be applied either globally, yielding two parameters, or separately for each of the five major decay channels, yielding ten parameters, $\kappa_{V}^f$ and $\kappa_{F}^f$ with the superscript $f$ indicating the decay mode. The best-fit values and uncertainties from a combined fit are

$$\kappa_V = 1.05 \pm 0.04$$
$$\kappa_F = 1.05 \pm 0.09.$$
FIG. 12. Negative log-likelihood contours at 68% and 95% CL in the ($\kappa_F$, $\kappa_F$) plane for the individual decay modes and their combination ($\kappa_F$ versus $\kappa_F$ shown in black) assuming the coupling strengths to fermions and vector bosons to be positive. No contributions from invisible or undetected Higgs boson decays are assumed. The best-fit value for each measurement is indicated by a cross while the SM hypothesis is indicated by a star.

FIG. 13. Negative log-likelihood contours at 68% and 95% CL in the ($\kappa_F$, $\kappa_F$) plane obtained from a combined fit, constraining all other coupling-strength modifiers to their SM values and assuming no contributions from invisible or undetected Higgs boson decays. The best-fit value for each measurement is indicated by a cross while the SM hypothesis is indicated by a star.

C. Probing BSM contributions in loops and decays

To probe contributions of new particles either through loops or new final states, the effective coupling strengths to photons and gluons $\kappa_F$ and $\kappa_g$ are measured. These parameters are defined to be positive as there is by construction no sensitivity to the sign of these coupling strengths. The modifiers corresponding to other loop-induced processes are resolved. The potential new particles contributing to these vertex loops may or may not contribute to the total width of the Higgs boson through direct invisible or undetected decays. In the former case, the total width is parameterized in terms of the branching fractions $B_{\text{inv}}$ and $B_{\text{undet}}$ defined in Sec. VII A. Furthermore, the benchmark models studied in this section assume that all coupling-strength modifiers of known SM particles are unity, i.e., they follow the SM predictions, and that the kinematics of the Higgs boson decay products are not altered significantly.

Assuming $B_{\text{inv}} = B_{\text{undet}} = 0$, the best-fit values and uncertainties from a combined fit are

$$\kappa_F = 1.00 \pm 0.06$$
$$\kappa_g = 1.03^{+0.07}_{-0.06}.$$

measured to be compatible with the SM expectation. The probability of compatibility between the SM hypothesis with the best-fit point corresponds to a $p$-value of $p_{\text{SM}} = 41\%$, computed using the procedure outlined in Sec. IV with two d.o.f. In the combined measurement a linear correlation of 44% between $\kappa_F$ and $\kappa_F$ is observed.

Figure 13 shows negative log-likelihood contours obtained from the combined fit in the ($\kappa_F$, $\kappa_F$) plane. Both $\kappa_F$ and $\kappa_g$ are measured to be compatible with the SM expectation. The probability of compatibility between the SM hypothesis with the best-fit point corresponds to a $p$-value of $p_{\text{SM}} = 88\%$, computed using the procedure outlined in Sec. IV with two d.o.f. A linear correlation of −44% between $\kappa_F$ and $\kappa_g$ is observed, in part due to the constraint on their product from the rate of $H \rightarrow \gamma\gamma$ decays in the ggF channel.

To also consider additional contributions to the total width of the Higgs boson, the assumption of no invisible or undetected decays is dropped and $B_{\text{inv}}$ and $B_{\text{undet}}$ are included as independent parameters in the model. The measurements sensitive to Higgs boson decays into invisible final states described in Sec. III H are included in the combination and used to constrain $B_{\text{inv}}$. The $B_{\text{undet}}$ parameter is constrained by decay modes that do not involve a loop process. The results from this model are

$$\kappa_F = 0.97 \pm 0.06$$
$$\kappa_g = 0.95 \pm 0.08$$

$$B_{\text{inv}} < 0.43 \text{ at } 95\% \text{ CL}$$
$$B_{\text{undet}} < 0.12 \text{ at } 95\% \text{ CL}.$$

Limits on $B_{\text{inv}}$ and $B_{\text{undet}}$ are set using the $t_\mu$ prescription presented in Sec. IV. The expected upper limits at 95% CL on $B_{\text{inv}}$ and $B_{\text{undet}}$ are 0.20 and 0.31 respectively. The probability of compatibility between the SM hypothesis with the best-fit point corresponds to a $p$-value of
p_{SM} = 19\%$, computed using the procedure outlined in Sec. IV with four d.o.f.

The results for both models are summarized in Fig. 14.

D. Generic parametrization assuming no new particles in loops and decays

In this model the scale factors for the coupling strengths to $W, Z, t, b, \tau$ and $\mu$ are treated independently. The Higgs boson couplings to second-generation quarks are assumed to scale as the couplings to the third-generation quarks. SM values are assumed for the couplings to first-generation fermions. Furthermore, it is assumed that only SM particles contribute to Higgs boson vertices involving loops, and modifications of the coupling-strength scale factors for fermions and vector bosons are propagated through the loop calculations. Invisible or undetected Higgs boson decays are assumed not to exist. All coupling-strength scale factors in this generic model are found to be positive. The results of the $H \rightarrow \mu\mu$ analysis are included for this specific benchmark model. The results are shown in Table X. The expected 95% CL upper limit on $\kappa_{\mu}$ is 1.79. All measured coupling-strength scale factors in this generic model are found to be compatible with their SM expectation. The probability of compatibility between the SM hypothesis with the best-fit point corresponds to a $p$-value of $p_{SM} = 78\%$, computed using the procedure outlined in Sec. IV with six d.o.f. Figure 15 shows the results of this benchmark model in terms of reduced coupling-strength scale factors, defined as

\[ y_{V} = \sqrt{\frac{g_{V}}{2}} = \frac{m_{V}}{v} \]

for weak bosons with a mass $m_{V}$, where $g_{V}$ is the absolute Higgs boson coupling strength and $v = 246$ GeV is the vacuum expectation value of the Higgs field, and

\[ y_{F} = \frac{g_{F}}{\sqrt{2}} = \frac{m_{F}}{v} \]

for fermions with mass $m_{F}$.

$\kappa_{F}$ is the absolute Higgs boson coupling strength and $v = 246$ GeV is the vacuum expectation value of the Higgs field, and $y_{F} = g_{F}/\sqrt{2} = m_{F}/v$ for fermions with mass $m_{F}$. The SM prediction for both cases is also shown (dotted line). The black error bars represent 68% CL intervals for the measured parameters. For $\kappa_{\mu}$, the light error bars indicate the 95% CL interval. The coupling modifiers $\kappa_{F}$ and $\kappa_{V}$ are measured assuming no BSM contributions to the Higgs boson decays, and the SM structure of loop processes such as $ggF, H \rightarrow \gamma\gamma$ and $H \rightarrow gg$. The lower inset shows the ratios of the values to their SM predictions.
for fermions with a mass $m_f$. For the $b$ quark and the top quark, the $\overline{\text{MS}}$ running mass evaluated at a scale of 125.09 GeV is used.

### E. Generic parametrization including effective photon and gluon couplings with and without BSM contributions in decays

The models considered in this section are based on the same parametrization as the one in Sec. VII D but the ggF, $H \to gg$ and $H \to \gamma\gamma$ loop processes are parameterized using the effective coupling-strength modifiers $\kappa_Z$ and $\kappa_{\gamma\gamma}$, similar to the benchmark model probed in Sec. VII C.

The measured parameters include $\kappa_Z$, $\kappa_W$, $\kappa_b$, $\kappa_t$, $\kappa_r$, $\kappa_f$, $\kappa_{\gamma\gamma}$, and $\kappa_{t}\kappa_{\gamma\gamma}$. The sign of $\kappa_t$ can be either positive or negative, while $\kappa_Z$ is assumed to be positive without loss of generality. All other model parameters are also assumed to be positive. Furthermore, it is assumed that the probed for BSM effects do not affect the kinematics of the Higgs boson decay products significantly. Three alternative scenarios are considered for the total width of the Higgs boson: (a) No BSM contributions to the total width ($B_{\text{inv}} = B_{\text{undet}} = 0$), (b) Both $B_{\text{inv}}$ and $B_{\text{undet}}$ are added as free parameters to the model. The measurements of Higgs boson decays into invisible final states described in Sec. III H are included in the combination, for these results only, and used to provide a constraint on $B_{\text{inv}}$. The conditions $\kappa_W \leq 1$ and $\kappa_Z \leq 1$ are used to provide a constraint on $B_{\text{undet}}$ as discussed in Sec. VII A.

(c) A single free parameter $B_{\text{BSM}} = B_{\text{inv}} + B_{\text{undet}}$ is added to the model. The measurements of off-shell production described in Sec. III I are included in the combination, for these results only, and used to provide a constraint on $B_{\text{BSM}}$ under the assumptions listed in Sec. VII A.

The numerical results for the various scenarios are summarized in Table XI and illustrated in Fig. 16. Limits on $B_{\text{inv}}$, $B_{\text{undet}}$ and $B_{\text{BSM}}$ are set using the $\tilde{t}_\alpha$ prescription presented in Sec. IV. All probed fundamental coupling-strength scale factors, as well as the probed loop-induced coupling scale factors are measured to be compatible with their SM expectation for all explored assumptions. Upper limits are set on the fraction of Higgs boson decays into invisible or undetected decays. In scenario (b) the observed (expected) 95% CL upper limits on the branching fractions are $B_{\text{inv}} < 0.30$ (0.16) and $B_{\text{undet}} < 0.21$ (0.36), and the lower limits on the couplings to vector bosons are $\kappa_Z > 0.88$ (0.76) and $\kappa_W > 0.85$ (0.77). In scenario (c), the observed (expected) upper limit on $B_{\text{BSM}}$ is 0.49 (0.51). The probability of compatibility between the SM hypothesis with the best-fit point in scenario (a) corresponds to a p-value of $p_{\text{SM}} = 88\%$, computed using the procedure outlined in Sec. IV with seven d.o.f.

### F. Generic parametrization using ratios of coupling modifiers

The five absolute coupling-strength scale factors and two effective loop-coupling scale factors measured in the previous benchmark model are expressed as ratios of scale factors that can be measured independent of any assumptions about the Higgs boson total width. The model parameters are defined in Table XII. All parameters are assumed to be positive. This parametrization represents the most model-independent determination of coupling-strength scale factors that is currently possible in the $\kappa$-framework. The numerical results from the fit to this benchmark model are summarized in Table XII and visualized in Fig. 17. All model parameters are measured to be compatible with their SM expectation. The probability of compatibility between the SM hypothesis with the best-fit

---

**TABLE XI.** Fit results for Higgs boson coupling modifiers per particle type with effective photon and gluon couplings and either $B_{\text{inv}} = B_{\text{undet}} = 0$, (b) $B_{\text{inv}}$ and $B_{\text{undet}}$ included as free parameters, the conditions $\kappa_W, \kappa_Z \leq 1$ applied and the measurement of the Higgs boson decay rate into invisible final states included in the combination, or (c) $B_{\text{BSM}} = B_{\text{inv}} + B_{\text{undet}}$ included as a free parameter, the measurement of off-shell Higgs boson production included in the combination, and the assumptions described in the text applied to the off-shell coupling-strength scale factors. The SM corresponds to $B_{\text{inv}} = B_{\text{undet}} = B_{\text{BSM}} = 0$ and all $\kappa$ parameters set to unity. All parameters except $\kappa_t$ are assumed to be positive.

the ggF loop unlike in sensitive to new colored particles contributing through H bosons into invisible final states included in the combination (red); or applied and the measurement of the Higgs boson decay rate of the SM. The measurements are interpreted in these benchmark models, providing indirect limits on their parameters that are complementary to those obtained by direct searches for new particles. The interpretations presented in this section follow the procedure discussed in Ref. [38].

A. Two-Higgs-doublet model

In 2HDMs, the SM Higgs sector is extended by introducing an additional complex isodoublet scalar field with weak hypercharge one. Four types of 2HDMs satisfy the Paschos–Glashow–Weinberg condition [159,160], which prevents the appearance of tree-level flavor-changing neutral currents:

(i) Type I: One Higgs doublet couples to fermion currents, while the other one couples to fermions. The first doublet is fermiophobic in the limit where the two Higgs doublets do not mix.

point corresponds to a $p$-value of $p_{SM} = 85\%$, computed using the procedure outlined in Sec. IV with seven d.o.f.

The parameter $\lambda_{WZ}$ in this model is of particular interest: identical coupling-strength scale factors for the $W$ and $Z$ bosons are required within tight bounds by the SU(2) custodial symmetry and the $\rho$ parameter measurements at LEP and at the Tevatron [149]. The ratio $\lambda_{WZ}$ is sensitive to new charged particles contributing to the $H \rightarrow \gamma\gamma$ loop unlike in $H \rightarrow ZZ'$ decays. Similarly, the ratio $\lambda_{tg}$ is sensitive to new colored particles contributing through the ggF loop unlike in $t\bar{t}H$ events. The observed values are in agreement with the SM expectation.

![ATLAS](image1)

**FIG. 16.** Best-fit values and uncertainties for Higgs boson coupling modifiers per particle type with effective photon and gluon couplings and either $B_{\text{inv}} = B_{\text{undet}} = 0$ (black); $B_{\text{inv}}$ and $B_{\text{undet}}$ included as free parameters, the conditions $\kappa_{W,Z} \leq 1$ applied and the measurement of the Higgs boson decay rate into invisible final states included in the combination (red); or $B_{\text{BSM}} = B_{\text{inv}} + B_{\text{undet}}$ included as a free parameter, the measurement of off-shell Higgs boson production included in the combination, and the assumptions described in the text applied to the off-shell coupling-strength scale factors (blue). The SM corresponds to $B_{\text{inv}} = B_{\text{undet}} = 0$ and all $\kappa$ parameters set to unity. All parameters except $\kappa_t$ are assumed to be positive.

![ATLAS](image2)

**FIG. 17.** Measured ratios of coupling modifiers. The dashed line indicates the SM value of unity for each parameter.
(ii) Type II: One Higgs doublet couples to up-type quarks and the other one to down-type quarks and charged leptons.

(iii) Lepton-specific: The Higgs bosons have the same couplings to quarks as in the Type I model and to charged leptons as in Type II.

(iv) Flipped: The Higgs bosons have the same couplings to quarks as in the Type II model and to charged leptons as in Type I.

The observed Higgs boson is identified with the light $CP$-even neutral scalar $h$ predicted by 2HDMs, and its accessible production and decay modes are assumed to be the same as those of the SM Higgs boson. Its couplings to vector bosons, up-type quarks, down-type quarks and leptons relative to the corresponding SM predictions are expressed as functions of the mixing angle $\alpha$ between $h$ and the heavy $CP$-even neutral scalar, and the ratio of the vacuum expectation values of the Higgs doublets, $\tan\beta$ [38].

Figure 18 shows the regions of the $(\cos(\beta - \alpha), \tan\beta)$ plane that are excluded at a confidence level of 95% or higher, for each of the four types of 2HDMs. The expected exclusion limits in the SM hypothesis are also overlaid. The data are consistent with the alignment limit [152] at $\cos(\beta - \alpha) = 0$, in which the couplings of $h$ match those of the SM Higgs boson, within one standard deviation or better in each of the tested models. The allowed regions also include narrow, curved petal regions at positive $\cos(\beta - \alpha)$ and moderate $\tan\beta$ in the Type II, lepton-specific,
and flipped models. These correspond to regions with \(\cos(\beta + \alpha) \approx 0\), for which some fermion couplings have the same magnitude as in the SM, but the opposite sign.

### B. Simplified minimal supersymmetric Standard Model

The scalar sector of the minimal supersymmetric Standard Model (MSSM) \([161–163]\) is a realization of a Type II 2HDM. As a benchmark, a simplified MSSM model in which the Higgs boson is identified with the light \(CP\)-even scalar \(h\), termed hMSSM \([164–166]\), is studied. The assumptions made in this model are discussed in Ref. [38]. Notably, the hMSSM is a good approximation of the MSSM only for moderate values of \(\tan\beta\). For \(\tan\beta \gtrsim 10\) the scenario is approximate due to missing supersymmetry corrections in the Higgs boson coupling to \(b\)-quarks, and for \(\tan\beta \approx O(1)\) the precision of the approximation depends on \(m_A\), the mass of the \(CP\)-odd scalar \([35]\). The production and decay modes accessible to \(h\) are assumed to be the same as those of the SM Higgs boson.

The Higgs boson couplings to vector bosons, up-type fermions and down-type fermions relative to the corresponding SM predictions are expressed as functions of the ratio of the vacuum expectation values of the Higgs doublets, \(\tan\beta\), \(m_A\), and the masses of the Z boson and of \(h\).

Figure 19 shows the regions of the hMSSM parameter space that are indirectly excluded by the measurement of the Higgs boson production and decay rates. The data are consistent with the SM decoupling limit at large \(m_A\), where the \(h\) couplings tend to those of the SM Higgs boson. The observed (expected) lower limit at 95% CL on the \(CP\)-odd Higgs boson mass is at least \(m_A > 480\) GeV \((m_A > 400\) GeV\) for \(1 \leq \tan\beta \leq 25\), increasing to \(m_A > 530\) GeV \((m_A > 450\) GeV\) at \(\tan\beta = 1\). The observed limit is stronger than the expected limit because the hMSSM model exhibits a physical boundary \(k_V \leq 1\), but the Higgs boson coupling to vector bosons is measured to be larger than the SM value, as presented in Sec. VII.

### IX. CONCLUSIONS

Measurements of Higgs boson production cross sections and branching fractions have been performed using up to \(79.8\) fb\(^{-1}\) of \(pp\) collision data produced by the LHC at \(\sqrt{s} = 13\) TeV and recorded by the ATLAS detector. The results presented in this paper are based on the combination of analyses of the \(H \rightarrow \gamma\gamma, H \rightarrow ZZ^*, H \rightarrow WW^*, H \rightarrow \tau\tau, H \rightarrow bb\) and \(H \rightarrow \mu\mu\) decay modes, searches for decays into invisible final states, as well as on measurements of off-shell Higgs boson production.

The global signal strength is determined to be \(\mu = 1.11^{+0.09}_{-0.08}\).

The Higgs boson production cross sections within the region \(|y_H| < 2.5\) are measured in a combined fit for the gluon–gluon fusion process, vector-boson fusion, the associated production with a W or Z boson and the associated production with top quarks, assuming the SM Higgs boson branching fractions. The combined measurement leads to an observed (expected) significance for the vector-boson fusion production process of 6.5\(\sigma\) (5.3\(\sigma\)). For the \(VH\) production mode the observed (expected) significance is 5.3\(\sigma\) (4.7\(\sigma\)). The \(t\bar{t}H + tH\) processes are measured with an observed (expected) significance of 5.8\(\sigma\) (5.3\(\sigma\)).

Removing the assumption of SM branching fractions, a combined fit is performed for the production cross section times branching fraction for each pair of production and decay processes to which the combined analyses are sensitive. Results are also presented for a model in which these quantities are expressed using the cross section of the \(gg \rightarrow H \rightarrow ZZ^*\) process, ratios of production cross sections relative to that of ggF production, and ratios of branching fractions relative to that of \(H \rightarrow ZZ^*\).

Cross sections are measured in 15 regions of Higgs boson production kinematics defined within the simplified template cross section framework, which primarily characterize the transverse momentum of the Higgs boson, the topology of associated jets and the transverse momentum of associated vector bosons. The measurements in all regions are found to be compatible with SM predictions.

The observed Higgs boson yields are used to obtain confidence intervals for \(\kappa\) modifiers to the couplings of the SM Higgs boson to fermions, weak vector bosons, gluons,
and photons and to the branching fraction of the Higgs boson into invisible and undetected decay modes. A variety of physics-motivated constraints on the Higgs boson total width are explored: Using searches for $H \to$ invisible and constraints on couplings to vector bosons, the branching fraction of invisible Higgs boson decays into BSM particles is constrained to be less than 30% at 95% CL, while the branching fraction of decays into undetected particles is less than 22% at 95% CL. The overall branching fraction of the Higgs boson into BSM decays is determined to be less than 47% at 95% CL using measurements of off-shell Higgs boson production in combination with measurements of SM Higgs boson production and rates. No significant deviation from the SM predictions is observed in any of the benchmark models studied.

Finally, the results are interpreted in the context of two-Higgs-doublet models and the hMSSM. Constraints are set in the $(m_A, \tan \beta)$ plane of the hMSSM and the $(\cos(\beta - \alpha), \tan \beta)$ plane in 2HDM Type-I, Type-II, lepton-specific and flipped models.

ACKNOWLEDGMENTS

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently. We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWFW and FWF, Austria; ANAS, Azerbaijan; STFC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF and DNSRC, Denmark; IN2P3-CNRS, CEA-DRF/IRFU, France; SRNSFG, Georgia; BMBF, HGF, and MPG, Germany; GSRT, Greece; RGC, Hong Kong SAR, China; ISF and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; NWO, Netherlands; RCN, Norway; MNiSW and NCN, Poland; FCT, Portugal; MNE/IFA, Romania; MES of Russia and NRC KI, Russian Federation; JINR; MESTD, Serbia; MSSR, Slovakia; ARRS and MIZŠ, Slovenia; DST/NRF, South Africa; MINECO, Spain; SRC and Wallenberg Foundation, Sweden; SERI, SNSF and Cantons of Bern and Geneva, Switzerland; MOST, Taiwan; TAEK, Turkey; STFC, United Kingdom; DOE and NSF, USA. In addition, individual groups and members have received support from BCKDF, CANARIE, CRC and Compute Canada, Canada; COST, ERC, ERDF, Horizon 2020, and Marie Skłodowska-Curie Actions, European Union; Investissements d’ Avenir Labex and Idex, ANR, France; DFG and AvH Foundation, Germany; Herakleitos, Thales and Aristeia programmes co-financed by EU-ESF and the Greek NSRF, Greece; BSF-NSF and GIF, Israel; CERCA Programme Generalitat de Catalunya, Spain; The Royal Society and Leverhulme Trust, United Kingdom. The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN, the ATLAS Tier-1 facilities at TRIUMF (Canada), NDCGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK) and BNL (USA), the Tier-2 facilities worldwide and large non-WLCG resource providers. Major contributors of computing resources are listed in Ref. [167].

APPENDIX: SIMPLIFIED TEMPLATE CROSS SECTION MEASUREMENT RESULTS WITH FINER GRANULARITY

This section presents measurements of STXS parameters in a model that has finer granularity than the model of Sec. VI B, and is thus closer to the original proposal of Stage 1 STXS in Refs. [35,36]. The changes relative to the model of Sec. VI B are as follows: in the $gg \to H$ process, the region defined by $p_T^H \geq 200 \text{ GeV}$ and $\geq 1$ jets is split into separate bins for 1 jet and $\geq 2$ jets; a VBF-topology (VBFTopo) (VBFTopo) region is defined for events with $\geq 2$ jets using...

![FIG. 20. Best-fit values and uncertainties for the cross sections in each measurement region times the $H \to ZZ^*$ branching fraction in a model with finer granularity. The results are shown normalized to the SM predictions for the various parameters. The black error bar shows the total uncertainty in each measurement.](012002-28)
FIG. 21. Correlation matrix for the measured values of the simplified template cross sections in each measurement region times the $H \to ZZ^*$ branching fraction in a model with finer granularity.

the same selection as in the $qq \to Hqq$ process; the remaining $\geq 2$ jet events are separated into three bins of $p_T^H$ in the same way as the 1-jet events; in the $qq \to Hqq$ process, the VBF topo+Rest region is split into separate bins for VBF topo and Rest; and in the $qq \to WH$ process, the $p_T^H < 250$ GeV region is split into two bins for $p_T^H < 150$ GeV and $150 \leq p_T^H < 250$ GeV, matching the binning used in $pp \to ZH$. The results are shown in Figs. 20 and 21.
