Abstract A search for the direct production of charginos and neutralinos in final states with at least two hadronically decaying tau leptons is presented. The analysis uses a dataset of $pp$ collisions corresponding to an integrated luminosity of 36.1 fb$^{-1}$, recorded with the ATLAS detector at the Large Hadron Collider at a centre-of-mass energy of 13 TeV. No significant deviation from the expected Standard Model background is observed. Limits are derived in scenarios of direct production of $\tilde{\chi}_1^\pm \tilde{\chi}_1^0$ pair production and of $\tilde{\chi}_1^\pm \tilde{\chi}_2^0$ and $\tilde{\chi}_1^0 \tilde{\chi}_1^-$ production in simplified models where the neutralinos and charginos decay solely via intermediate left-handed staus and tau sneutrinos, and the mass of the $\tilde{\tau}_L$ state is set to be halfway between the masses of the $\tilde{\chi}_1^0$ and the $\tilde{\chi}_1^+$. Chargino masses up to 630 GeV are excluded at 95% confidence level in the scenario of direct production of $\tilde{\chi}_1^0 \tilde{\chi}_1^-$ for a massless $\tilde{\chi}_1^0$. Common $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$ masses up to 760 GeV are excluded in the case of production of $\tilde{\chi}_1^\pm \tilde{\chi}_2^0$ and $\tilde{\chi}_1^0 \tilde{\chi}_1^-$ assuming a massless $\tilde{\chi}_1^0$. Exclusion limits for additional benchmark scenarios with large and small mass-splitting between the $\tilde{\chi}_1^\pm$ and the $\tilde{\chi}_1^0$ are also studied by varying the $\tilde{\tau}_L$ mass between the masses of the $\tilde{\chi}_1^\pm$ and the $\tilde{\chi}_1^0$.

1 Introduction

Supersymmetry (SUSY) [1–7] postulates the existence of a superpartner, referred to as a sparticle, whose spin differs by one half unit from each corresponding Standard Model (SM) partner. In models that conserve $R$-parity [8], sparticles are always produced in pairs, and the lightest supersymmetric particle (LSP) is stable and provides a dark-matter candidate [9–11].

In SUSY models, the sector of sparticles with only electroweak interactions contains charginos ($\tilde{\chi}_i^\pm$, $i = 1, 2$ in order of increasing masses), neutralinos ($\tilde{\chi}_j^0$, $j = 1, 2, 3, 4$ in order of increasing masses), sleptons ($\tilde{l}$), and sneutrinos ($\tilde{\nu}$). Charginos and neutralinos are the mass eigenstates formed from the linear superpositions of the superpartners of the charged and neutral Higgs bosons and electroweak gauge bosons. The sleptons are the superpartners of the leptons and are referred to as left or right ($\tilde{\ell}_L$ or $\tilde{\ell}_R$) depending on the chirality of their SM partners. The slepton mass eigenstates are a mixture of $\tilde{\ell}_L$ and $\tilde{\ell}_R$, and are labelled as $\tilde{\ell}$ (with $\tilde{\ell}_k$, $k = 1, 2$ in order of increasing masses). In this work, only the $\tilde{\chi}_1^\pm$, the $\tilde{\chi}_2^0$, the $\tilde{\chi}_1^0$, and the scalar superpartner of the left-handed tau lepton (the stau, $\tilde{\tau}_L$) and of the tau neutrino (the tau sneutrino, $\tilde{\nu}_\tau$) are assumed to be sufficiently light to be produced at the Large Hadron Collider (LHC) [12].

Although experimentally challenging, final states with tau leptons originating from stau decays are of particular interest for SUSY searches. Models with light staus can lead to a dark-matter relic density consistent with cosmological observations [13], and light sleptons in general could play a role in the co-annihilation of neutralinos [14, 15]. Sleptons are expected to have masses of $O(100 \text{ GeV})$ in gauge-mediated [16–21] and anomaly-mediated [22, 23] SUSY breaking models.

Scenarios where the production of charginos, neutralinos, and sleptons may dominate at the LHC with respect to the production of squarks and gluinos can be realised in the general framework of the phenomenological Minimal Supersymmetric Standard Model (pMSSM) [24, 25]. Two simplified models [26–28] of $\tilde{\chi}_1^\pm \tilde{\chi}_1^0$ and $\tilde{\chi}_1^\pm \tilde{\chi}_2^0$ production are considered in this work. The models are designed to enhance the probability of experimental observation. In both models, the lightest neutralino is the LSP and purely bino, the stau and tau sneutrino are assumed to be mass-degenerate, and the $\tilde{\tau}_L$ is assumed to be purely $\tilde{\tau}_L$. The mass of the $\tilde{\tau}_L$ state is set to be halfway between the masses of the $\tilde{\chi}_1^\pm$ and the $\tilde{\chi}_1^0$, i.e. $m(\tilde{\tau}_L) = m(\tilde{\chi}_1^0) + x \cdot (m(\tilde{\chi}_1^\pm) - m(\tilde{\chi}_1^0))$, with the parameter $x = 0.5$. Other values of $x$ are also studied for selected

* e-mail: atlas.publications@cern.ch
benchmark models where \( x \) is varied between 0.05 and 0.95 in steps of 0.1. All particles other than those explicitly mentioned here are assumed to be inaccessible at the LHC energy.

In the model characterised by \( \tilde{\chi}_1^\pm \tilde{\chi}_2^0 \) production, the \( \tilde{\chi}_1^\pm \) and \( \tilde{\chi}_2^0 \) are assumed to be pure wino and mass-degenerate. In the model where only \( \tilde{\chi}_1^\pm \tilde{\chi}_1^- \) production is considered, the \( \tilde{\chi}_1^\pm \) is pure wino. The above assumptions guarantee large production cross sections and short decay chains for \( \tilde{\chi}_1^\pm \) and \( \tilde{\chi}_2^0 \). Charginos and next-to-lightest neutralinos decay into the lightest neutralino via an intermediate on-shell stau or tau sneutrino, \( \tilde{\chi}_1^\pm \rightarrow \tilde{\nu}_\tau (\tilde{\tau}_\tau) \rightarrow \nu_\tau (\nu_\tau) \tilde{\chi}_1^0 \), \( \tilde{\chi}_2^0 \rightarrow \tilde{\tau} \rightarrow \tau \tilde{\chi}_1^0 \), and \( \tilde{\chi}_2^0 \rightarrow \tilde{\nu}_\tau \nu_\tau \rightarrow \nu_\tau \nu_\tau \tilde{\chi}_1^0 \) (see Fig. 1).

Signal events are characterised by the presence of at least two tau leptons and large missing transverse energy, \( E_T^{\text{miss}} \), due to the undetected neutrinos and lightest neutralinos. Final states with at least two hadronically decaying tau leptons (\( \tau \rightarrow \text{hadrons} \nu_\tau \)) are considered, as this choice provides the best discrimination of SUSY events of interest from SM background processes (mainly multi-jet, WW + jets and diboson production). In multi-jet events passing the selection requirements described in Sect. 5, nearly all reconstructed tau leptons are misidentified jets. \( W(\rightarrow \tau \nu_\tau) + \) jets events contribute due to the \( E_T^{\text{miss}} \) from the neutrino, one tau lepton from the \( W \) decay, and one or more jets misidentified as tau leptons. The jet misidentification typically results in a mismeasurement of \( E_T^{\text{miss}} \), which tends to assume large values. Diboson events with WW or ZZ decaying into \( \tau\tau \nu\nu \) final states contain two tau leptons and large \( E_T^{\text{miss}} \) from the neutrinos.

The search described in this paper uses a dataset of \( \sqrt{s} = 13 \) TeV pp collisions collected with the ATLAS detector in 2015 and 2016, with an integrated luminosity of 36.1 fb\(^{-1}\). In a previous similar search by the ATLAS Collaboration using the 8 TeV Run-1 dataset [29], \( \tilde{\chi}_1^\pm \) masses up to 345 GeV were excluded at 95\% confidence level for a massless \( \tilde{\chi}_1^0 \) in the scenario of direct production of \( \tilde{\chi}_1^\pm \tilde{\chi}_1^- \). In the case of production of \( \tilde{\chi}_1^\pm \tilde{\chi}_2^0 \) and \( \tilde{\chi}_1^\pm \tilde{\chi}_1^- \), common \( \tilde{\chi}_1^\pm \) and \( \tilde{\chi}_2^0 \) masses up to 410 GeV were excluded for a massless \( \tilde{\chi}_1^0 \). Results of a similar search in the Run-1 dataset from the CMS Collaboration are reported in Refs. [30,31]. In Ref. [30], charginos lighter than 320 GeV are excluded at 95\% confidence level in the case of a massless \( \tilde{\chi}_1^0 \). The combined LEP limits on the stau and chargino masses are \( m_{\tilde{\tau}} > 87–93 \) GeV (depending on \( m_{\tilde{\chi}_1^0} \)) and \( m_{\tilde{\chi}_1^+} > 103.5 \) GeV [32–36], respectively.

2 ATLAS detector

The ATLAS detector [37] is a multi-purpose particle physics detector with forward-backward symmetric cylindrical geometry and nearly 4\( \pi \) coverage in solid angle.\(^1\) It features an inner tracking detector (ID) surrounded by a 2 T superconducting solenoid, electromagnetic and hadronic calorimeters, and a muon spectrometer (MS). The ID covers the pseudorapidity region \( |\eta| < 2.5 \) and consists of a silicon pixel detector, a silicon microstrip detector, and a transition radiation tracker. One significant upgrade for the \( \sqrt{s} = 13 \) TeV running period is the presence of the insertable B-Layer [38], an additional pixel layer close to the interaction point which provides high-resolution hits at small radius to improve the tracking and vertex reconstruction performance. The calorimeters are composed of high-granularity liquid-argon (LAr) electromagnetic calorimeters with lead, copper, or tungsten absorbers (in the pseudorapidity region \( |\eta| < 3.2 \)) and a steel–scintillator hadronic calorimeter (for \( |\eta| < 1.7 \)). The end-cap and forward regions, spanning 1.5 \( < |\eta| < 4.9 \), are instrumented with LAr calorimeters for both the electromagnetic and hadronic measurements. The MS surrounds the calorimeters and consists of three large superconducting air-core toroidal magnets, each with eight coils, a system of precision tracking chambers (\( |\eta| < 2.7 \)), and detectors for triggering (\( |\eta| < 2.4 \)). A two-level trigger system is used to record events [39].

3 Data and simulated event samples

The analysed dataset, after the application of beam, detector, and data quality requirements, corresponds to an integrated luminosity of 36.1 fb\(^{-1}\) of pp collision data recorded in 2015 and 2016 at \( \sqrt{s} = 13 \) TeV. The uncertainty in the combined

---

\(^1\) For the interval \( 0.1 \leq \Delta m (\tilde{\chi}_1^\pm, \tilde{\chi}_1^0) \leq 3 \) GeV, the chargino mass limit set by LEP degrades to 91.9 GeV.

\(^2\) ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the centre of the detector, and the \( z \)-axis along the beam line. The \( x \)-axis points from the IP to the centre of the LHC ring, and the \( y \)-axis points upwards. Cylindrical coordinates \((r, \phi)\) are used in the transverse plane, \( \phi \) being the azimuthal angle around the \( z \)-axis. Observables labelled \textit{transverse} refer to the projection into the \( x-y \) plane. The pseudorapidity is defined in terms of the polar angle \( \theta \) by \( \eta = -\ln(\tan(\theta/2)) \).
2015 + 2016 integrated luminosity is 3.2%. It is derived, following a methodology similar to that detailed in Ref. [40], from a preliminary calibration of the luminosity scale using $x - y$ beam-separation scans performed in August 2015 and May 2016.

Monte Carlo (MC) simulated event samples are used to estimate the SUSY signal yields and to aid in evaluating the SM backgrounds. Generated SM events are processed through a detailed detector simulation [41] based on GEANT 4 [42], whereas SUSY events are passed through a fast detector simulation based on a parameterisation of the performance of the ATLAS electromagnetic and hadronic calorimeters [43] and GEANT 4 elsewhere. All simulated events are overlaid with multiple $pp$ collisions (pile-up) simulated with the soft strong interaction processes of PYTHIA 8.186 [44] using the A2 set of tuned parameters [45] and the MSTW2008LO [46] PDF set. The simulated events are reconstructed using the same algorithms as the data, and are reweighted so that the distribution of the expected number of collisions per bunch crossing matches the one in the data.

3.1 Simulated background samples

Events with $Z/\gamma^* \rightarrow \ell\ell$ ($\ell = e, \mu, \tau$) and $W \rightarrow \ell v$ produced with accompanying jets (including light and heavy flavours) were generated at next-to-leading order (NLO) in the strong coupling constant with SHERPA 2.2.0 and 2.2.1 [47,48]. Matrix elements (ME) were calculated for up to two additional partons at NLO and four additional partons at leading order (LO), using the Comix [49] and OpenLoops [50] generators and merged with the SHERPA parton shower (PS) [51] using the ME + PS@NLO prescription [48]. The NNPDF3.0NNLO [52] parton distribution function (PDF) set was used in conjunction with a dedicated parton-shower tuning developed by the SHERPA authors. The $W/Z$ + jets events were normalised using their next-to-next-to-leading order (NNLO) cross sections [53]. For SHERPA 2.2.0 samples, a simplified scale setting prescription was used in the multi-parton matrix elements, to improve the event generation speed.

The fully leptonic diboson processes ($VV = WW/WZ/ZZ$) were generated using SHERPA 2.2.1 including final states with all possible combinations of charged leptons and neutrinos. The matrix elements contain all diagrams with four electroweak vertices, and they were calculated for up to one parton ($4\ell, 2\ell + 2v, ZZ, WW$) or no additional parton ($3\ell + 1v, 1\ell + 3v, WZ$) at NLO and up to three partons at LO. The NNPDF3.0NNLO PDF set was used in conjunction with a dedicated PS tuning developed by the SHERPA authors. Diboson processes with one of the bosons decaying hadronically and the other leptonically were simulated using the SHERPA 2.1.1 event generator. The matrix elements are calculated for up to one (ZZ) or no (WW, WZ) additional partons at NLO and up to three additional partons at LO. The CT10 [54] PDF set was used in conjunction with a dedicated PS tuning developed by the SHERPA authors. Each of the diboson processes was normalised using the corresponding NLO cross section [55].

The production of top-quark pairs and single top quarks in the $Wt$ and $s$-channels was performed with POWHEG-BOX 2 [56], with the CT10 PDF set in the ME calculations. Electroweak $t$-channel single-top-quark events were generated using the POWHEG-BOX 1 event generator. The PS, fragmentation, and the underlying event were simulated using PYTHIA 6.428 [57] with the CTEQ6L1 PDF set and a corresponding set of tuned parameters called the Perugia 2012 tune [58]. The EvtGen 1.2.0 program [59] was used for properties of the bottom and charm hadron decays. The top-quark mass was set to 172.5 GeV. The overall cross section was computed at NNLO in $a_s$, including resummation of next-to-next-to-leading-logarithm (NNLL) soft gluon terms [60] for $tt\bar{t}$, to NLO + NNLL accuracy for single-top-quark $Wt$-channel [61], and to NLO for the $t$- and $s$-channels [62]. Top-quark pair production with an additional $W$ or $Z$ boson was performed using MADGRAPH5_aMC@NLO 2.2.0 and 2.2.1 [47,48], while fragmentation and hadronisation were simulated with PYTHIA 8.186. The ATLAS underlying-event tune A14 [64] was used with the NNPDF2.3LO [65] PDF set, and the cross sections were normalised using NLO [66,67].

3.2 Simulated signal samples

Simulated signal samples were generated using MADGRAPH5_aMC@NLO 2.2.3 interfaced to PYTHIA 8.186 with the A14 tune for the PS modelling, hadronisation, and underlying event. The ME calculation is performed at tree level and includes the emission of up to two additional partons. The PDF set used for the generation is NNPDF2.3LO. The ME–PS matching used the CKKW-L [68] prescription, with a matching scale set to one quarter of the mass of the pair of produced particles. Signal cross sections were calculated to next-to-leading order in the strong coupling constant, adding the resummation of soft gluon emission at next-to-leading-logarithm accuracy (NLO + NLL) [69,70]. The nominal cross section and the uncertainty were taken from an envelope of cross-section predictions using different PDF sets and factorisation and renormalisation scales, following the procedure described in Ref. [71].

Two simplified models characterised by $\tilde{\chi}^\pm_1 \tilde{\chi}^{0}_1$ and $\tilde{\chi}^{\pm}_1 \tilde{\chi}^{0}_2$ production are considered. The neutralinos and charginos decay via intermediate staus and tau neutrinos. In both models, the $\tilde{\chi}^\pm_1$ mass is varied between 100 GeV and 1.1 TeV in steps of 50 (100) GeV for $\tilde{\chi}^\pm_1$ masses smaller (larger) than 700 GeV. The $\tilde{\chi}^{0}_1$ mass is varied between zero and 500 GeV with a variable spacing of 25 (50) GeV for $\tilde{\chi}^\pm_1$ and $\tilde{\chi}^{0}_1$ masses.
considered \cite{79}. Jets are required to have $p_T > 20$ GeV and $|\eta| < 2.5$. A working point with an average $b$-tagging efficiency of 77% for simulated $t\bar{t}$ events is used \cite{81,82}. The expected rejection factors for light-quark and gluon jets, $c$-quark jets, and hadronically decaying tau leptons are approximately 134, 6, and 55, respectively.

Electron candidates are reconstructed by matching clusters in the electromagnetic calorimeter with charged-particle tracks in the inner detector. Electrons are required to have $p_T > 10$ GeV and $|\eta| < 2.47$, and to satisfy the ‘loose’ working point according to a likelihood-based identification \cite{83}. Muon candidates are reconstructed from MS tracks matching ID tracks. Muons are required to have $p_T > 10$ GeV and $|\eta| < 2.7$ and fulfill the ‘medium’ quality criteria of Ref. \cite{84}. Events containing a muon candidate with a poorly measured charge-to-momentum ratio ($\sigma(q/p)/|q/p| > 0.2$) are rejected. Events are required not to contain any candidate muon with large impact parameter ($|d_0| > 1$ mm or $|d_0| > 0.2$ mm), as it may originate from cosmic rays. The efficiencies for electrons and muons to satisfy the reconstruction, identification, and isolation criteria are measured in samples of leptonic $Z$ and $J/\psi$ decays, and corrections are applied to the simulated samples to reproduce the efficiencies in data.

The reconstruction of hadronically decaying tau leptons is based on information from tracking in the ID and three-dimensional clusters in the electromagnetic and hadronic calorimeters. The tau reconstruction algorithm is seeded by jets reconstructed as described above but with $p_T > 10$ GeV and $|\eta| < 2.5$. The reconstructed energies of the hadronically decaying tau candidates are corrected to the tau energy scale, which is calibrated based on simulation and in-situ measurements using $Z \rightarrow \tau\tau$ decays. Tau neutrinos from the tau lepton decay are not taken into account in the reconstruction and calibration of the tau energy and momentum. Hadronic tau decay candidates are required to have one or three associated charged-particle tracks (prongs) and the total electric charge of those tracks must be ±1 times the electron charge. To improve the discrimination between hadronically decaying tau leptons and jets, electrons, or muons, multivariate algorithms are used \cite{85}. The tau identification algorithm is based on a boosted decision tree (BDT) method. The BDT algorithms use various track and cluster variables as input to discriminate tau leptons from jets. For 1-prong (3-prong) tau candidates, the signal efficiencies are 60% (50%), 55% (40%), and 45% (30%) for the ‘loose’, ‘medium’, and ‘tight’ working points, respectively. In the following, tau candidates are required to satisfy the medium identification criteria for jet discrimination (‘medium’ tau candidates), unless otherwise stated. For electron discrimination, an overlap-based veto is used for 1-prong tau candidates. This requirement has about 95% efficiency, and a rejection factor from 10 to 50 depending on the $\eta$ range. Tau candidates are required to have $p_T > 20$ GeV and $|\eta| < 2.47$, excluding the tran-

4 Event reconstruction

Events with at least one reconstructed primary vertex \cite{72} are selected. A primary vertex must have at least two associated charged-particle tracks with transverse momentum $p_T > 400$ MeV and be consistent with the beam spot envelope. If there are multiple primary vertices in an event, the one with the largest $\sum p_T^2$ of the associated tracks is chosen.

Jets are reconstructed from three-dimensional calorimeter energy clusters \cite{73} using the anti-$k_t$ algorithm \cite{74,75} with a radius parameter of 0.4. Jet energies are corrected for detector inhomogeneities, the non-compensating response of the calorimeter, and the impact of pile-up, using factors derived from test beam and $pp$ collision data, and from a detailed GEANT 4 detector simulation \cite{76,77}. The impact of pile-up is accounted for using a technique, based on jet areas, that provides an event-by-event and jet-by-jet correction \cite{78}. Jets that are likely to have originated from pile-up are not considered \cite{79}. Jets are required to have $p_T > 20$ GeV and $|\eta| < 2.8$. Events containing jets that are likely to have arisen from detector noise or cosmic rays are removed.

Jets containing $b$-hadrons ($b$-jets) are identified using the MV2c10 algorithm, a multivariate discriminant making use of track impact parameters and reconstructed secondary vertices \cite{80}. Candidate $b$-jets are required to have $p_T > 20$ GeV and $|\eta| < 2.5$. A working point with an average $b$-tagging efficiency of 77% for simulated $t\bar{t}$ events is used \cite{81,82}. The expected rejection factors for light-quark and gluon jets, $c$-quark jets, and hadronically decaying tau leptons are approximately 134, 6, and 55, respectively.

Electron candidates are reconstructed by matching clusters in the electromagnetic calorimeter with charged-particle tracks in the inner detector. Electrons are required to have $p_T > 10$ GeV and $|\eta| < 2.47$, and to satisfy the ‘loose’ working point according to a likelihood-based identification \cite{83}. Muon candidates are reconstructed from MS tracks matching ID tracks. Muons are required to have $p_T > 10$ GeV and $|\eta| < 2.7$ and fulfill the ‘medium’ quality criteria of Ref. \cite{84}. Events containing a muon candidate with a poorly measured charge-to-momentum ratio ($\sigma(q/p)/|q/p| > 0.2$) are rejected. Events are required not to contain any candidate muon with large impact parameter ($|d_0| > 1$ mm or $|d_0| > 0.2$ mm), as it may originate from cosmic rays. The efficiencies for electrons and muons to satisfy the reconstruction, identification, and isolation criteria are measured in samples of leptonic $Z$ and $J/\psi$ decays, and corrections are applied to the simulated samples to reproduce the efficiencies in data.

The reconstruction of hadronically decaying tau leptons is based on information from tracking in the ID and three-dimensional clusters in the electromagnetic and hadronic calorimeters. The tau reconstruction algorithm is seeded by jets reconstructed as described above but with $p_T > 10$ GeV and $|\eta| < 2.5$. The reconstructed energies of the hadronically decaying tau candidates are corrected to the tau energy scale, which is calibrated based on simulation and in-situ measurements using $Z \rightarrow \tau\tau$ decays. Tau neutrinos from the tau lepton decay are not taken into account in the reconstruction and calibration of the tau energy and momentum. Hadronic tau decay candidates are required to have one or three associated charged-particle tracks (prongs) and the total electric charge of those tracks must be ±1 times the electron charge. To improve the discrimination between hadronically decaying tau leptons and jets, electrons, or muons, multivariate algorithms are used \cite{85}. The tau identification algorithm is based on a boosted decision tree (BDT) method. The BDT algorithms use various track and cluster variables as input to discriminate tau leptons from jets. For 1-prong (3-prong) tau candidates, the signal efficiencies are 60% (50%), 55% (40%), and 45% (30%) for the ‘loose’, ‘medium’, and ‘tight’ working points, respectively. In the following, tau candidates are required to satisfy the medium identification criteria for jet discrimination (‘medium’ tau candidates), unless otherwise stated. For electron discrimination, an overlap-based veto is used for 1-prong tau candidates. This requirement has about 95% efficiency, and a rejection factor from 10 to 50 depending on the $\eta$ range. Tau candidates are required to have $p_T > 20$ GeV and $|\eta| < 2.47$, excluding the tran-
sition region between the barrel and end-cap calorimeters (1.37 < |η| < 1.52).

The simulation is corrected for differences in the efficiencies of the tau identification at both trigger and reconstruction level between data and simulation. For hadronically decaying tau leptons originating from prompt gauge boson decays, the corrections are calculated with a tag-and-probe method in a sample of $Z \rightarrow \tau \tau$ events where one tau lepton decays hadronically and the other leptonically into a muon and two neutrinos [86].

The measurement of the missing transverse momentum vector, $p_T^{\text{miss}}$, and its magnitude, $E_T^{\text{miss}}$, is based on the negative vectorial sum of the $p_T$ of all identified jets, tau candidates, electrons, photons, muons, and an additional soft term. The soft term is constructed from all high-quality tracks that are associated with the primary vertex but not with any identified particle or jet. In this way, the missing transverse momentum is adjusted for the best calibration of the jets and the other identified particles, while maintaining pile-up independence in the soft term [87,88].

With the reconstruction methods described above, it is possible that the same observables (tracks, calorimetric clusters) are assigned to several objects. This possible double counting of reconstructed objects is resolved in the following order. Tau candidates close to electron or muon candidates ($\Delta R < 0.2$, where $\Delta R = \sqrt{(\Delta y)^2 + (\Delta \phi)^2}$ ) are removed, as are electrons that share a track with a muon. For electrons close to a jet ($\Delta R < 0.4$), the electron is removed, except when $\Delta R < 0.2$ and the jet is not $b$-tagged, in which case the jet is removed. Any remaining jet within $\Delta R = 0.4$ of a muon or tau candidate is removed.

5 Event selection

The events used in this analysis passed either an asymmetric di-tau trigger or a combined di-tau + $E_T^{\text{miss}}$ trigger. The asymmetric di-tau trigger requires the identification of two hadronically decaying tau candidates with $p_{T, \tau_1} > 85$ GeV and $p_{T, \tau_2} > 50$ GeV at trigger level for the leading and next-to-leading tau candidates respectively. Two tau candidates with $p_{T, \tau_1} > 35$ GeV and $p_{T, \tau_2} > 25$ GeV at trigger level, and $E_T^{\text{miss}} > 50$ GeV (at uncalibrated electromagnetic scale) are required by the di-tau + $E_T^{\text{miss}}$ trigger. In events selected by the di-tau + $E_T^{\text{miss}}$ trigger, the reconstructed $E_T^{\text{miss}}$ must be larger than 150 GeV. The trigger efficiency for correctly identified tau leptons is $\sim 80\%$ for events where, at reconstruction level, the leading tau candidate has $p_T > 95$ (50) GeV, and the next-to-leading tau candidate has $p_T > 65$ (40) GeV for the asymmetric di-tau (di-tau + $E_T^{\text{miss}}$) trigger.

Events are required to have at least two tau candidates with opposite electric charge. The reconstructed mass of any opposite-sign (OS) tau pair must be larger than 12 GeV to remove tau leptons originating from decays of low-mass resonances. This requirement has negligible effect on the signal efficiency. Two of the reconstructed tau candidates must satisfy the $p_T$ requirements to be in the region where the trigger efficiency is constant (see Table 1).

To further discriminate the SUSY signal events from SM background processes, additional requirements are applied to define the signal region (SR) selections. To reject events from SM processes containing a top quark, selected events must not contain any $b$-tagged jet ($b$-jet veto). To suppress SM backgrounds with a $Z$ boson, events are selected by requiring that the reconstructed mass of all oppositely charged tau pairs, $m(\tau_1, \tau_2)$, must not be within 10 GeV of the mean visible $Z$ boson mass $m_Z$ (79 GeV). This requirement is referred to as the $Z$-veto. An upper bound on the transverse mass $m_{T2}$ [89,90] is imposed to reduce contributions from $t\bar{t}$ and $WW$ events. The $m_{T2}$ variable is defined as:

$$m_{T2} = \min_{q_T} \left[ \max \left( m_{T, \tau_1} (p_T, q_T), m_{T, \tau_2} (p_T, q_T, p_T^{\text{miss}} - q_T) \right) \right],$$

where $p_{T, \tau_1}$ and $p_{T, \tau_2}$ are the transverse momenta of the two tau candidates, and $q_T$ is the transverse momentum vector that minimises the larger of the two transverse masses $m_{T, \tau_1}$ and $m_{T, \tau_2}$. The latter masses are defined by

$$m_T(p_T, q_T) = \sqrt{2(p_T q_T - p_T \cdot q_T)}.$$ 

In events where more than two tau candidates are selected, $m_{T2}$ is computed among all possible tau pairs and the combination leading to the largest value is chosen. For $t\bar{t}$ and $WW$ events, in which two $W$ bosons decay leptonically and $p_T^{\text{miss}}$ is the sum of the transverse momenta of the two neutrinos, the $m_{T2}$ distribution has a kinematic end-point at the $W$ mass. For large mass differences between the next-to-lightest neutralinos, the charginos, or the staus and the lightest neutralino, the $m_{T2}$ distribution for signal events extends significantly beyond this end-point.

Two SRs based on large $m_{T2}$ and $E_T^{\text{miss}}$ requirements are defined. SR-lowMass (SR-highMass) is designed to cover signal models where the mass difference between the $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_1^0$ is smaller (larger) than 200 GeV. In SR-lowMass, only the di-tau + $E_T^{\text{miss}}$ trigger is used. This trigger has high efficiency in selecting events with tau leptons originating from $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$ decays in models where the mass difference between the parent particle and the $\tilde{\chi}_1^0$ is small. The main discriminating requirement is $m_{T2} > 70$ GeV.

3 The mean visible $Z$ boson mass is defined as the mean value of a Gaussian fit of the reconstructed mass distribution of OS tau pairs in a MC sample of $Z \rightarrow \tau \tau$ events with associated jets.
In SR-highMass, events are selected by the di-tau+$E_T^{miss}$ trigger or by the asymmetric di-tau trigger. If the event is selected by the di-tau+$E_T^{miss}$ trigger, the leading tau candidate threshold is raised to $p_T,\tau_1 > 80$ GeV. If the event is selected by the asymmetric di-tau trigger, $E_T^{miss} > 110$ GeV is required. At least one of the tau candidates must satisfy the tight identification criteria for jet discrimination ('tight' tau candidate). In addition, the two leading tau candidates must satisfy $m(\tau_1, \tau_2) > 110$ GeV and $m_{T2} > 90$ GeV. The requirements for both SRs are summarised in Table 1. The two SRs are not mutually exclusive.

### 6 Standard model background estimation

The main SM processes contributing to the selected final states are multi-jet, $W$ + jets and diboson production. Background events may contain a combination of ‘real’ tau leptons, defined as correctly identified prompt tau leptons, or ‘fake’ tau leptons, which can originate from a misidentified light-flavour quark or gluon jet, an electron, or a muon.

In multi-jet events nearly all tau candidates are misidentified jets. The multi-jet contribution in the SRs is estimated from data, as described in Sect. 6.1. The contribution arising from heavy-flavour multi-jet events containing a real tau lepton from the heavy-flavour quark decay is included in the multi-jet estimate. The contribution of $W$ + jets events, which contain one real tau lepton from the $W$ decay and one or more misidentified jets, is estimated from MC simulation and normalised to data in a dedicated control region (CR), as described in Sect. 6.2.

Diboson production contributes mainly with events containing real tau leptons originating from $WW$ and $ZZ$ decaying into a $\tau\tau\nu\nu$ final state. Additional SM backgrounds arise from $Z$ + jets production, or events that contain a top quark or a top-quark pair in association with jets or additional $W$ or $Z$ bosons (collectively referred to as top background in the following). The contribution from real tau leptons exceeds 90% in $Z$ + jets and diboson production, and ranges from 45% to 75% in backgrounds containing top quarks according to the MC simulation. The contribution of fake tau leptons from heavy-flavour decays in jets is found to be negligible in MC simulation. To estimate the irreducible background, which includes diboson, $Z +$ jets and top events, only MC simulated samples are used, as described in Sect. 6.3.

The sources of systematic uncertainty in the background estimates are described in Sect. 7. For each signal region a simultaneous fit based on the profile likelihood method [91] is performed to normalise the multi-jet and $W +$ jets background estimates and propagate systematic uncertainties, as described in Sect. 6.4.
more, two sets of validation regions (VR), VR-E and VR-F, are defined corresponding to each SR. The validation regions are used to verify the extrapolation of the ABCD estimation to the SRs and to estimate the systematic uncertainty from the residual correlation between the tau identification and charge requirements, and the kinematic variables $m_{T2}$ and $E_T^{miss}$.

In all validation regions and both sets of CR-B and CR-C, the events passed a di-tau trigger instead of the di-tau + $E_T^{miss}$ trigger, due to the low $E_T^{miss}$ requirements. The di-tau trigger requires the identification of two hadronically decaying tau candidates with transverse momenta exceeding the same set of thresholds as described in Sect. 5 for the di-tau + $E_T^{miss}$ trigger. The di-tau trigger was prescaled during all 2016 data-taking.

The number of multi-jet events in the control and validation regions is estimated from data after subtraction of other SM contributions estimated from MC simulation. In both CR-B and VR-E, more than 86% of the events come from multi-jet production, whereas for CR-A and CR-C the multi-jet purity is larger than 47 and 68%, respectively. In VR-F the multi-jet purity is larger than 90%. Agreement between data and the estimated SM background is found for the $E_T^{miss}$ and $m_{T2}$ distributions in the validation regions, as shown in Fig. 3. The correlation between the tau identification and charge and the kinematic variables is checked by studying the variation of the transfer factor $T$ as a function of the kinematic

### Table 2 Definition of the regions used in the ABCD method for the multi-jet estimation in SR-lowMass (left) and SR-highMass (right). Only those requirements that are different in the CRs/VRs with respect to the SRs are listed

The results of the ABCD method are summarised in Table 3. The signal contamination in a certain region is defined as the ratio of the number of signal events to the sum of the number of signal events and SM background processes. The signal contamination in CR-A for both SRs ranges from a few percent to 30–50% for a few signal models, and it is taken into account in the simultaneous fit described in Sect. 6.4. The largest contaminations are found for a \( \tilde{\chi}^\pm_1 \) mass of 400 GeV and massless \( \tilde{\chi}^0_1 \) for \( \tilde{\chi}^\pm_1 \tilde{\chi}^\mp_1 \) production, and for a \( \tilde{\chi}^\mp_1 \) mass of 300 GeV and massless \( \tilde{\chi}^0_1 \) for \( \tilde{\chi}^\pm_1 \tilde{\chi}^\mp_2 \) production. The possible presence of non-SM event contamination in CR-A was tested and proved not to change the fit results significantly.

### 6.2 \( W + \) jets background estimation

The production of \( W + \) jets events with at least one misidentified tau lepton is an important background, accounting for about 13% (20%) of the expected SM background in SR-lowMass (SR-highMass). A dedicated control region (\( W \)-CR) is used to normalise the \( W + \) jets MC estimate to data. To suppress multi-jet contamination, the \( W \)-CR is enriched in events where the \( W \) boson decays leptonically into a muon...
Table 3 The MC predicted backgrounds in the multi-jet control regions, including the statistical uncertainties, and the expected multi-jet contribution (in italics), obtained by subtracting the MC contributions from observed data (in bold). Predicted event yields for the SUSY reference points (defined in Sect. 3) in the control regions are also shown. The estimated multi-jet contribution in the SRs is given in the last column including both the statistical and systematic uncertainties. The details of the systematic uncertainties reported here are discussed in Sect. 7.

The multi-jet contribution in the W-CR (W-VR) is estimated using the so-called OS–SS method by counting the number of events in data satisfying the same requirements as the W-CR (W-VR) but with the electric charge of the two leptons having the same sign (SS). Events from SM processes other than multi-jet production are subtracted from the data counts in the SS region using MC simulation. The OS–SS method relies on the fact that in the multi-jet background the ratio of SS to OS events is close to unity, while a significant difference from unity is expected for W + jets production. The latter is dominated by $g\mu/gd$-initiated processes that often give rise to a jet originating from a quark, the charge of which is anti-correlated with the W boson charge. Based on studies with simulated samples, a systematic uncertainty of 100% is assigned to the multi-jet estimate in the W-CR.

The event yields in the W-CR and W-VR are given in Table 5. The purity of the selection in W + jets events and a neutrino. Events are selected with a single-muon trigger, using the lowest unprescaled $p_T$ thresholds available. Events containing exactly one isolated muon and one candidate tau lepton with opposite electric charge are selected. The muon is required to have $p_T > 40$ GeV. In addition, the muon must satisfy the ‘GradientLoose’ [84] isolation requirements, which rely on the use of track and calorimeter based variables and implement a set of $η$- and $p_T$-dependent criteria. Compatibility of the signal lepton tracks with the primary vertex is enforced by requiring $|z_0 \sin \theta| < 0.5$ mm, where $z_0$ is the longitudinal impact parameter. In addition, the transverse impact parameter, $d_0$, divided by its uncertainty, $\sigma(d_0)$, must satisfy $|d_0/\sigma(d_0)| < 3$ for the muon. The tau candidate must satisfy the medium tau identification criteria and is required to have $p_T > 50$ GeV.

The contribution from events with top quarks is suppressed by rejecting events containing $b$-tagged jets. To reduce the contribution from $Z +$ jets production, the transverse mass of the $μ + E_T^{\text{miss}}$ system, $m_{T, μ} > 50$ GeV, the sum of the transverse mass of the $τ + E_T^{\text{miss}}$ and $μ + E_T^{\text{miss}}$ systems, $m_{T, τ} + m_{T, μ} > 80$ GeV, and the angular separation between the muon and the tau lepton $ΔR(μ, τ) > 0.5$ are required. To further suppress diboson and top-quark contributions, $m_{T, μ} < 150$ GeV is required. To be close to the SR definition, $E_T^{\text{miss}} > 60$ GeV and the invariant mass of the muon and tau lepton, $m(μ, τ) > 70$ GeV are required. Events in the W-CR are selected by requiring low $m_{T2}$, while a high $m_{T2}$ region is used to validate the W + jets estimate (W validation region, W-VR). The definitions of the W-CR and W-VR are given in Table 4.
is around 72% (77%) in the W-CR (W-VR). Agreement between data and SM predictions is observed. The signal contamination in the W-CR and W-VR is negligible. Distributions of the kinematic variables defining the SRs are shown in Fig. 4, in which the contribution of W + jets events is scaled with the normalisation factor 1.02 obtained from the fit described in Sect. 6.4. The discrepancy between observed data and predictions at $m_{T2} > 90$ GeV in the W-VR is due to events with different kinematics from the SRs, with either $E_T^{miss} < 150$ GeV or where the muon has $p_T < 60$ GeV.

6.3 Irreducible background estimation

Irreducible SM backgrounds arise mainly from $t\bar{t}$, single top quark, $t\bar{t}+V$, $Z +$ jets, and diboson ($WW$, $WZ$ and $ZZ$) processes and are estimated with MC simulation. Other SM backgrounds are negligible.

The inclusive contribution from $t\bar{t}$, single top quark, $t\bar{t}+V$ and $Z +$ jets amounts to about 18% (13%) of the total background in SR-highMass (SR-lowMass). The MC estimates are validated in regions enriched in $Z +$ jets and top-quark events. For both regions, the events passed either the combined di-tau + $E_T^{miss}$ trigger or the asymmetric di-tau trigger. Events are required to have at least two tau candidates with opposite electric charge, $E_T^{miss} > 150$ GeV, and leading (sub-leading) tau $p_T > 50$ (40) GeV. In the $Z +$ jets validation region (Z-VR), at least two tau candidates must satisfy the medium tau identification criteria. To suppress top-quark backgrounds, events containing $b$-tagged jets are vetoed. To further enhance the purity of $Z +$ jets events, $m_{T2} < 10$ GeV is required. In the top-quark validation region (Top-VR), at least one tau candidate must satisfy the medium tau identification criteria. To increase the contribution from top-quark events, events must contain at least one $b$-tagged jet with $p_T > 20$ GeV and must be kinematically compatible with $t\bar{t}$ production (top-tagged) through the use of the transverse mass $m_{CT}$ [92]. The scalar sum of the $p_T$ of the two tau leptons and of at least one combination of two jets in an event must exceed 100 GeV. Top-tagged events are required to possess $m_{CT}$ values calculated from combinations of jets and tau leptons consistent with the expected bounds from $t\bar{t}$ events as described in Ref. [93]. The Z-VR and Top-VR requirements are summarised in Table 6.

The diboson background accounts for 26% (43%) of the total SM contribution in the SR-highMass (SR-lowMass) and mainly arises from $WW \rightarrow \tau\nu\tau\nu$ and $ZZ \rightarrow \tau\tau\nu\nu$ events, in which more than 96% of the contribution is from events with two real tau leptons according to the MC simulation. To validate the MC modelling and normalisation of the $WW$ ($ZZ$) process, a validation region $W$-$VR$ ($ZZ$-$VR$) with an enriched $WW \rightarrow e\mu\nu\nu$ ($ZZ \rightarrow e\mu\nu\nu$ or $ZZ \rightarrow \mu\mu\nu\nu$) contribution is defined. For $WW$-$VR$, events with two isolated leptons ($\ell = e$ or $\mu$) with different flavour and opposite sign are selected, while for $ZZ$-$VR$, events with two isolated leptons with same flavour and opposite sign are selected. To keep the phase space similar to the SRs, $WW$-$VR$ ($ZZ$-$VR$) is defined to be close to the SRs except for the selected objects being a light-lepton pair. Top-tagged events are vetoed to suppress the $t\bar{t}$ contribution in $WW$-$VR$. To suppress the $Z +$ jets contribution in $ZZ$-$VR$, $\Delta R(\ell, \ell) < 1.5$ is applied; the requirement $|m_{\ell\ell} - m_Z| < 15$ GeV is used to enrich the $ZZ$ contribution. The definitions of $WW$-$VR$ and $ZZ$-$VR$ are summarised in Table 7.

The purity of the selection in $Z +$ jets and $t\bar{t}$ events is above 80% in the respective validation regions, and the purity of the selection in $WW$ ($ZZ$) events is around 65% (92%) in $WW$-$VR$ ($ZZ$-$VR$). Agreement between data and the SM prediction is observed in all validation regions. The $m_{T2}$ distributions in the Z-VR, Top-VR, $WW$-$VR$ and $ZZ$-$VR$ are shown in Fig. 5.

### Table 6

6.4 Statistical analysis

The statistical interpretation of the results is performed using the profile likelihood method implemented in the HistFitter framework [94]. Three types of fits are performed for each SR.

- The background-only fit uses as input the number of observed events in the multi-jet CR-A and W-CR, the expected SM contributions other than multi-jet to the multi-jet CR-A and W-CR, and the transfer factors,
Fig. 4 The $E^\text{miss}_T$ (left) and $m_{T^2}$ (right) distributions in the $W$-CR (top) and $W$-VR (bottom) regions. The SM backgrounds other than multi-jet production are estimated from MC simulation. The contribution of $W$ + jets events is scaled to the fit result. The multi-jet contribution is estimated from data using the OS–SS method. The hatched bands represent the combined statistical and systematic uncertainties of the total SM background. For illustration, the distributions of the SUSY reference points defined in Sect. 3 are also shown as dashed lines. The lower panels show the ratio of data to the SM background estimate. The last bin includes the overflow events.

</table>
which are used to extrapolate the background of multi-jet or $W + \text{jets}$ events in their control regions to these predicted in the signal regions. The free parameters in the fit are the normalisations of the $W + \text{jets}$ and multi-jet contributions. The signal is assumed to be absent in this fit.

A model-independent limit fit combines the data event yield in a given SR with the SM background estimate and its uncertainties obtained by the background-only fit to test whether any non-SM signal contributes to the SR. The significance of a possible excess of observed events over the SM prediction is quantified by the one-sided probability, $p(\text{signal} = 0)$ denoted by $p_0$, of the background alone to fluctuate to the observed number of events or higher using the asymptotic formula described in Ref. [91]. The presence of a non-SM signal would manifest itself in a small $p_0$ value.

In the model-dependent limit fit the SUSY signal is allowed to populate both the signal and the control regions, and it is scaled by a freely floating signal normalisation factor. The background normalisation factors are also determined simultaneously in the fit. A SUSY model with a specific set of sparticle masses is rejected if the upper limit at 95% confidence level (CL) of the
signal normalisation factor obtained in this fit is smaller than unity.

The likelihood function is a product of the probability density functions, one for each region contributing to the fit. The number of events in a given CR or SR is described using a Poisson distribution, the mean of which is the sum of the expected contributions from all background and signal sources. The systematic uncertainties in the expected event yields are included as nuisance parameters and are assumed to follow a Gaussian distribution with a width determined from the size of the uncertainty. Correlations between control and signal regions, and background processes are taken into account with common nuisance parameters. The fit parameters are determined by maximising the product of the Poisson probability functions and the constraints for the nuisance parameters.

7 Systematic uncertainties

Systematic uncertainties have an impact on the estimates of the background and signal event yields in the control and signal regions. Uncertainties arising from experimental effects and theoretical sources are estimated.

The main sources of experimental systematic uncertainty in the SM background estimates include tau lepton and jet energy calibrations and resolution, tau lepton identification, pile-up, and uncertainties related to the modelling of \( E_{\text{T}}^{\text{miss}} \) in the simulation. The uncertainties in the energy and momentum scale of each of the objects entering the \( E_{\text{T}}^{\text{miss}} \) calculation are estimated, as well as the uncertainties in the soft-term resolution and scale. A variation in the pile-up reweighting of the MC simulated event samples is included to cover the uncertainty in the ratio of the predicted and measured inelastic cross section in the fiducial volume defined by \( M_X > 13 \) GeV where \( M_X \) is the mass of the hadronic system [95]. The main contributions to experimental systematic uncertainties in the SR-lowMass (SR-highMass) are from the tau lepton identification and energy scale around 6% (8%), jet energy scale and resolution around 11% (4%), \( E_{\text{T}}^{\text{miss}} \) soft-term resolution and scale around 2% (6%), and pile-up around 8% (8%). Other contributions are less than 5%.

Theoretical uncertainties affecting the MC event generator predictions are estimated by varying the renormalisation, factorisation, and resummation scales, and the matching scale between the matrix elements and the parton shower. For \( W + \text{jets} \) and diboson processes, the uncertainties related to the choice of the QCD renormalisation and factorisation scales are estimated from the comparison of the nominal samples with samples with these scales varied up and down by a factor of two. Uncertainties in the resummation scale and the matching scale between the matrix elements and parton shower are evaluated by varying up and down the corresponding parameters in SHERPA by a factor of two. For \( W + \text{jets} \) events, the uncertainty due to the jet \( p_T \) threshold used for parton–jet matching is estimated by comparing the baseline samples with jet \( p_T \) threshold set to 20 GeV to samples with a threshold of 15 or 30 GeV. SHERPA is compared with MADGRAPH to estimate the uncertainty related to the generator choice for \( W + \text{jets} \) production. The total theoretical uncertainty for diboson processes in the SRs is around 15%, mainly coming from the choice of QCD renormalisation scale (4–9%) and resummation scale (around 10%). The theory uncertainty in \( W + \text{jets} \) production is 13–20%, and the main source is the event generator uncertainty (4–17%) and the QCD renormalisation scale (9–10%). An overall systematic uncertainty of 6% in the inclusive cross section is assigned to the diboson process. Based on previous studies [29], a total theoretical uncertainty of 25% is assigned for the top-quark and \( Z + \text{jets} \) contributions to the SRs.

The following sources of uncertainty are considered for the ABCD method used to determine the multi-jet background: the correlation between the tau-id, the charge requirement, and the kinematic variables \( m_T^2 \), the limited number of events in the CRs, and the subtraction of other SM backgrounds. The systematic uncertainty in the correlation is estimated by comparing the transfer factor from CR-B to CR-C to that of VR-E to VR-F. The systematic uncertainty in the non-multi-jet background subtraction in the control regions is estimated by considering the systematic uncertainty of the MC estimates of the non-multi-jet background in the CRs. Both uncertainties are of the order of 10%. The systematic uncertainty in the signal region due to the limited number of events in the control regions is estimated by taking the statistical uncertainty of the event yields in these control regions. It corresponds to the largest source of uncertainty for the ABCD method, and it reaches 21–42% for CR-A.

The systematic uncertainties on the background estimates in the SRs are summarised in Table 8. The dominant uncertainties are the multi-jet background normalisation (around 32% in both SR-lowMass and SR-highMass), and the statistical uncertainty of the MC predictions (around 18% in SR-lowMass and 24% in SR-highMass respectively).

The total uncertainty in the signal yields for the SUSY reference points defined in Sect. 3 is about 20%. The main sources of experimental uncertainty are the tau lepton identification and energy scale, jet energy scale and resolution, \( E_{\text{T}}^{\text{miss}} \) soft-term resolution and scale, and pile-up: they amount to a total of about 15%. The cross-section uncertainty is taken into account as main source of theoretical uncertainty, and it varies from 3 to 20% for the considered SUSY
models. SUSY models with higher chargino mass have larger uncertainties.

8 Results

The observed number of events in each signal region and the expected contributions from SM processes are given in Table 9. The contributions of multi-jet and $W + j$ets events are scaled with the normalisation factors obtained from the background-only fit described in Sect. 6.4. The multi-jet normalisation with respect to the prediction from the ABCD method in the SR-lowMass (SR-highMass) is compatible with unity and has an uncertainty of around 100% (86%), due to the small number of observed events in the multi-jet CR-A. The $W + j$ets normalisation is 1.02 ± 0.15. The $m_{T2}$ distribution is shown in Fig. 6 for data, expected SM backgrounds, and the SUSY reference points defined in Sect. 3. In both signal regions, observations and background predictions are found to be compatible within uncertainties.

Upper limits at 95% CL on the number of non-SM events in the SRs are derived from the model-independent fit. All limits are calculated using the CL$_S$ prescription [96]. Normalising these by the integrated luminosity of the data sample, they can be interpreted as upper limits on the visible non-SM cross section, $\sigma_{\text{vis}}$, which is defined as the product of acceptance, reconstruction efficiency and production cross section. The accuracy of the limits obtained from the asymptotic formula was tested for all SRs by randomly generating a large number of pseudo-datasets and repeating the fit. Good agreement was found.

9 Interpretation

In the absence of a significant excess over the expected SM background, the observed and expected numbers of events in the signal regions are used to place exclusion limits at 95% CL using the model-dependent limit fit described in Sect. 6.4. SR-highMass is used to derive limits on $\tilde{\chi}^+_1 \tilde{\chi}^-_1$ production and the best limit expected for SR-highMass and SR-lowMass is used to derive limits on the production of $\tilde{\chi}^0_1 \tilde{\chi}^+_1$ and $\tilde{\chi}^0_1 \tilde{\chi}^-_1$. The exclusion limits for simplified models with $x = 0.5$, described in Sect. 3, are shown in Fig. 7. Only $\tilde{\chi}^+_1 \tilde{\chi}^-_1$ production is assumed for the left plot, whereas both production processes are considered simultaneously for the right plot. The solid (dashed) lines show the observed (expected) exclusion contours. The band around the expected limit shows the ±1σ variations, including all uncertainties except theoretical uncertainties in the signal cross section. The dotted lines around the observed limit indicate the sensitivity to ±1σ variations of the theoretical uncertainties in the signal cross section.

Chargino masses up to 630 GeV are excluded for a massless lightest neutralino in the scenario of direct production of chargino pairs. In the case of production of chargino pairs and mass-degenerate charginos and next-to-lightest neutralinos, chargino masses up to 760 GeV are excluded for a massless lightest neutralino. Both limits apply to scenarios where

the neutralinos and charginos decay solely via intermediate staus and tau sneutrinos, and with the parameter $x$ equal to 0.5. These limits significantly extend previous results [29,30] in the high chargino mass region.

The impact of $x$ different from 0.5 is studied by varying it between 0.05 and 0.95 for two benchmark scenarios. The CL$_s$ significance as a function of the parameter $x$ is shown in Fig. 8. When only $\tilde{\chi}_1^±\tilde{\chi}_1^-$ production is considered, the benchmark scenario with large mass-splitting ($m(\tilde{\chi}_1^±) = 600$ GeV and massless $\tilde{\chi}_1^0$) can be excluded for $x$ up to 0.75. For larger values of $x$ the $p_T$ spectra of the tau leptons from the chargino decay become very soft. The compressed benchmark scenario ($m(\tilde{\chi}_1^±) = 250$ GeV and $m(\tilde{\chi}_1^0) = 100$ GeV) can only be excluded for the extreme cases with $x = 0.05$ or $x = 0.95$, since the $m_{T2}$ requirement is more effective for models with large mass-splittings between the charginos or the staus and the lightest neutralino. Models with low values of $x$ typically predict dark-matter relic density consistent with cosmological observations. For combined production of $\tilde{\chi}_1^±\tilde{\chi}_1^-\tilde{\chi}_2^0$ and $\tilde{\chi}_1^±\tilde{\chi}_2^+$ the same general features are observed, but due to the higher signal yields with respect to $\tilde{\chi}_1^±\tilde{\chi}_1^-$ production alone, both benchmark scenarios can be excluded for all considered values of $x$.

10 Conclusion

Searches for the electroweak production of supersymmetric particles in events with at least two hadronically decaying tau leptons are performed using 36.1 fb$^{-1}$ of $pp$ collision data at $\sqrt{s} = 13$ TeV recorded with the ATLAS experiment at the Large Hadron Collider. Agreement between data and SM predictions is observed in two optimised signal regions. The results are used to set limits on the visible cross section of systematic and statistical uncertainties of the total SM background. For illustration, the distributions of the SUSY reference points (defined in Sect. 3) are also shown as dashed lines. The lower panels show the ratio of data to the total SM background estimate. The last bin includes the overflow events.

The observed limits for the benchmark scenarios indicate the position of the cut in the signal region. The stacked histograms show the expected SM backgrounds. The multi-jet contribution is estimated from data using the ABCD method. The contributions of multi-jet and $W + jets$ events are scaled with the corresponding normalisation factors. The hatched bands represent the sum in quadrature of systematic and statistical uncertainties of the total SM background.
The 95% CL exclusion contours for simplified models with $\tilde{\chi}^+\tilde{\chi}_1^-$ production (left) and production of $\tilde{\chi}^+\tilde{\chi}_1^-$ and $\tilde{\chi}^\pm_0\tilde{\chi}_2^0$ (right). The text provides details of exclusion curves and uncertainty bands.

The LEP limit on the chargino mass is also shown. Results are compared with the observed limits obtained by previous ATLAS searches [29] as blue contours.

Fig. 7 The 95% CL exclusion contours for simplified models with $\tilde{\chi}^+\tilde{\chi}_1^-$ production (left) and production of $\tilde{\chi}^+\tilde{\chi}_1^-$ and $\tilde{\chi}^\pm_0\tilde{\chi}_2^0$ (right). The text provides details of exclusion curves and uncertainty bands.

Fig. 8 The $C_{\text{L}}$ significance for the benchmark models described in Sect. 3 as a function of the parameter $x$. The benchmark scenario with large mass splitting ($m(\tilde{\chi}_1^0, \tilde{\chi}_2^0) = 600$ GeV and $m(\tilde{\chi}_1^\pm) = 0$ GeV) is shown on the right, and the compressed benchmark scenario ($m(\tilde{\chi}_1^0, \tilde{\chi}_2^0) = 250$ GeV and $m(\tilde{\chi}_1^\pm) = 100$ GeV) on the left, for $\tilde{\chi}^+\tilde{\chi}_1^-$ production (top), and $\tilde{\chi}^+\tilde{\chi}_1^-$ and $\tilde{\chi}^\pm_0\tilde{\chi}_2^0$ production (bottom). SR-highMass is used for $\tilde{\chi}^+\tilde{\chi}_1^-$ production, while the SR with the best expected $C_{\text{L}}$ value for each point of the parameter space is used for $\tilde{\chi}^+\tilde{\chi}_1^-$ and $\tilde{\chi}^\pm_0\tilde{\chi}_2^0$ production.
mass-degenerate charginos and next-to-lightest neutralinos, common $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$ masses up to 760 GeV are excluded for a massless lightest neutralino. The additional benchmark scenarios with small and large mass-splitting can be both excluded for all considered values of $x$.
