Search for Higgs Boson Decays into a Z Boson and a Light Hadronically Decaying Resonance Using 13 TeV pp Collision Data from the ATLAS Detector

G. Aad et al.*
(ATLAS Collaboration)

(Received 7 April 2020; accepted 9 October 2020; published 25 November 2020)

A search for Higgs boson decays into a Z boson and a light resonance in two-lepton plus jet events is performed, using a pp collision dataset with an integrated luminosity of 139 fb⁻¹ collected at √s = 13 TeV by the ATLAS experiment at the CERN LHC. The resonance considered is a light boson with a mass below 4 GeV from a possible extended scalar sector or a charmonium state. Multivariate discriminants are used for the event selection and for evaluating the mass of the light resonance. No excess of events above the expected background is found. Observed (expected) 95% confidence-level upper limits are set on the Higgs boson production cross section times branching fraction to a Z boson and the signal resonance, with values in the range 17−340 pb (16.5±320±130 pb) for the different light spin-0 boson mass and branching fraction hypotheses, and with values of 110 and 100 pb (100±30 and 100±30 pb) for the ηc and J/ψ hypotheses, respectively.

DOI: 10.1103/PhysRevLett.125.221802

The structure of the standard model (SM) scalar sector is the subject of intense scrutiny by the ATLAS [1] and CMS [2] Collaborations at the CERN Large Hadron Collider (LHC) [3]. At the current level of precision, all of the measured properties of the Higgs boson (H) [4,5] are found to be consistent with their SM predictions [6–10], and no additional Higgs boson has been observed to date. However, given the small natural decay width of the Higgs boson, even small additional contributions from physics beyond the SM can lead to final states with substantial, and thus possibly detectable, branching fractions (B) [11]. This Letter presents a search for Higgs boson decays into a Z boson and a hadronically decaying light resonance in events with a same-flavor lepton pair (electrons or muons) and a jet in the ATLAS detector. Hadronic decays of an ηc or of a J/ψ charmonium resonance (Q), or of a light spin-0 boson from an extended Higgs sector with a mass up to 4 GeV, are considered and are reconstructed as a single jet.

The Yukawa sector of the SM [12] does not provide an explanation for the observed fermion mass hierarchy. As a result, a wide range of new physics scenarios have been proposed, including the Froggatt-Nielsen mechanism [13] and the Higgs-dependent Yukawa couplings model [14]; for a recent overview, see Ref. [15]. The couplings of the Higgs boson to the third-generation fermions [16–21] have been observed, and a program to probe its couplings to the first- and second-generation charged leptons has been established [22–25]. For its couplings to first- and second-generation quarks, several approaches are being explored. Focusing on the Higgs boson’s coupling to the charm quark, direct searches have been performed for Higgs boson decays into charm quarks [26,27] and for exclusive decays into a J/ψ and a photon [28,29], with no excess observed. Constraints from differential cross section measurements of Higgs boson production versus transverse momentum (pT) have also been derived [30,31]. Higgs boson decays into a gauge boson and a charmonium state, including an ηc or a J/ψ, have been proposed as another way to access the coupling of the Higgs boson to the charm quark [32–34] and to probe the nature of the Higgs boson [35]. This search follows the last approach and maximizes the signal acceptance by focusing on inclusive hadronic final states of the mesons in H → Zηc and H → ZJ/ψ decays, which have SM branching fractions of 1.4 × 10⁻⁵ and 2.2 × 10⁻⁶ [35], respectively.

While the SM posits a single complex Higgs doublet field [36,37], extended Higgs sectors are motivated [38] and provide a rich phenomenology of additional scalars. Two such models discussed here are the two-Higgs-doublet model (2HDM) [11,39] and the 2HDM with an additional scalar singlet (2HDM + S) [11,40]. These represent two of the simplest extensions of the scalar sector, and with their type-II fermion couplings they are necessary to generate the masses in the minimal supersymmetric SM and the next-to-minimal supersymmetric SM, respectively [41]. Both of these models can include additional light pseudoscalars (a) with significant B(H → Za) or B(H → aa) [11]. In the

2HDM(+$\Sigma$), these two $B$ values can be adjusted independently, therefore searches for $H \rightarrow aa$ do not constrain $B(H \rightarrow Za)$, so that searches for the latter decay are required [11,34]. Despite the Yukawa nature of the $a$ to fermion couplings, there are large regions of parameter space depending on the mass of $a$ and the ratio of the vacuum expectation values of the two Higgs-doublet fields ($\tan \beta$) [11], where these pseudoscalars decay mainly to gluons and light up-type quarks, as the decays into down-type fermions are suppressed. These experimental signatures are also relevant in axion models [42–44], models of electroweak baryogenesis [45], neutrino mass models [46], dark-matter models [46,47], and models of grand unification [48]. Previous searches for Higgs boson decays into light scalars have been performed at the Tevatron [49] and the LHC [50–59]. However, these were mostly focused on searches for $H \rightarrow aa$, in final states including leptons, photons, or bottom quarks. By targeting the classification performance over the full mass range.

MLP-based mass estimator, which results in improved resonance-mass-related information from a separate range of masses considered, the classifier is provided with center-of-mass energy collision dataset, produced between 2015 and 2018 at a light scalars have been performed at the Tevatron [49] and section [48]. Previous searches for Higgs boson decays into gluons and light up-type quarks, as the decays into down-type quarks. By targeting the classification performance over the full mass range.

This search is performed using the complete run 2 $pp$ collision dataset, produced between 2015 and 2018 at a center-of-mass energy $\sqrt{s} = 13$ TeV by the LHC. The data were collected by the ATLAS detector [1] and correspond to an integrated luminosity of 139 fb$^{-1}$.

Monte Carlo (MC) samples of simulated events are used to model the signal selection efficiency. The signal samples were generated via the gluon-gluon fusion process using POWHEG-BOX v2 [64–66], with the CT10 next-to-leading order (NLO) parton distribution function (PDF) set [67]. Particle decays, hadronization, parton showers, and the underlying event were modeled using PYTHIA v8.212 [68] and EvtGen v1.6.0 [69], interfaced to the AZNLO [70] set of tuned parameters and the CTEQ6.1 PDF set [71]. Next-to-next-to-leading order (NNLO) corrections are applied to the $p_T$ distribution of the Higgs boson. The $a$ branching fractions were determined using PYTHIA 8 [68] with a 2HDM tan$\beta$ value of 1, which predicts $a \rightarrow gg$ to be the dominant decay mode until $a \rightarrow c\bar{c}$ becomes kinematically accessible. The signal MC samples used in this analysis...
opposite-sign electrons or muons are required to pass this selection and have an invariant mass compatible with the mass of the Z boson: $81 < m_{\ell\ell} < 101$ GeV. If multiple same-flavor opposite-sign lepton pairs fulfill this requirement, the pairing with an invariant mass closest to that of the Z boson is chosen. $Z \rightarrow \tau\tau$ decays are reconstructed through the leptonic decays of the $\tau$ leptons.

The hadronically decaying resonance is reconstructed as a single jet using the anti-$k_{t}$ jet algorithm [89,90] with a radius parameter of 0.4, formed from topological calorimeter energy clusters [91,92] and calibrated to the electromagnetic energy scale. Jet energies are corrected for contributions from simultaneous inelastic $pp$ interactions (pileup) using a jet-area-based technique [93,94] and calibrated [95,96] using $p_T$ and $\eta$-dependent correction factors determined from simulation, with residual corrections from in situ measurements applied to data and internal jet properties. Jets are required to have $p_T > 20$ GeV and $|\eta| < 2.5$ and satisfy a jet cleaning requirement [97]. To reject jets from pileup interactions, jets with $p_T < 60$ GeV and $|\eta| < 2.4$ are required to pass a “jet vertex tagger” [79] requirement. An overlap removal procedure resolves cases in which multiple electrons, muons, or jets are reconstructed from the same detector signature. Higgs boson candidates are reconstructed from the lepton pair and jet system, which is required to have an invariant mass passing a loose preselection requirement: $m_{\ell\ell} < 250$ GeV. If multiple jets satisfy these requirements, the jet with the highest $p_T$ is selected. The acceptance for this preselection, evaluated using generator-level MC samples, varies between 28% and 29% for the different $Q/a$ signal hypotheses.

MLPs [63] are used to select signal events passing this preselection. The MLP input variables are built using tracks matched to the calorimeter jet by ghost association [93], in which the tracks are included in the jet clustering process as with negligible energy and their angles from the jet axis. This allows the MLP to benefit from the high resolution of the tracking detector. These tracks must have $p_T > 500$ MeV and $|\eta| < 2.5$ and pass loose quality and track-to-vertex association requirements [98] to reject fake tracks from the reconstruction and tracks from pileup, respectively. Six dimensionless variables are constructed using these tracks: the ratio of the $p_T$ of the highest $p_T$ track to the $p_T$ of the ghost-associated track system; the angular separation $\Delta R$ between the highest-$p_T$ track and the calorimeter jet axis; NSubJettiness 2 [99], using exclusive-$k_t$ subjet axes with radius parameters of 0.2, and a jet axis radius parameter of 0.4; angularity(2) [100]; and $U_1(0.7)$ and $M_2(0.3)$, which are modified energy correlation functions [101] designed for quark-gluon discrimination and to target two-pronged substructure, respectively. These variables primarily capitalize on the presence of a narrow resonance or two-pronged substructure in the track system. Initially, a regression MLP [63], using four hidden layers of 12 nodes, is trained using the above input variables and the $a$ signal samples to estimate the mass of $a$, as shown in Fig. 1(a). This estimated mass is then

FIG. 1. Output of (a) the regression and (b) the classification MLPs, for data, background, and three signal hypotheses. Events are required to pass the complete event selection, including the $120 < m_{\ell\ell} < 135$ GeV requirement, but not the requirement on the classification MLP output variable. The background normalization is set equal to that of the data, and the signal normalizations assume the SM Higgs boson inclusive production cross section and $B(H \rightarrow Za) = 100\%$, and in (a) the signal normalization is scaled up by a factor of 100. The error bars (hatched regions) represent the data (MC) sample statistical uncertainty, in both the histograms and the ratio plots. In (b) the region to the right of the dashed line is the signal region.
provided alongside the six input variables to a classification MLP [63], to inform the classifier about the part of the hadronic resonance mass spectrum where the specific event lies. This classification MLP has two hidden layers of six and five nodes and is trained using the 4 signal samples and the background samples. The 0.75 GeV a signal sample is excluded from the training of the classification MLP to ensure an even spacing between the a mass hypotheses, so the training is not biased toward lower masses. Both MLPs use sigmoidal response functions with summed inputs and are trained using backpropagation with a mean-square estimator [63], as these resulted in optimal discrimination without overtraining. The addition of the regression MLP was found to result in a 13% improvement in the $S/\sqrt{B}$ of the classification MLP, where $S$ and $B$ are the expected numbers of signal and background events passing the MLP requirement, respectively. The classification MLP output variable ($M$) is shown in Fig. 1(b).

The signal region (SR) for this search is defined by the requirements 120 < $m_{ll}$ < 135 GeV and $M$ > 0.0524, chosen to maximize the expected $S/\sqrt{B}$, averaged over the various a mass hypotheses. The efficiency of this MLP requirement for events passing the preselection is (0.761 ± 0.020)% for the background, (5.89 ± 0.24)% and (6.66 ± 0.26)% for $H \rightarrow Z\eta_c$ and $H \rightarrow ZJ/\psi$, respectively, and between (1.88 ± 0.15)% and (45.9 ± 0.8)% for $H \rightarrow Z\eta_c$. The efficiencies for the complete selection are estimated using MC samples and are (0.545 ± 0.022)% and (0.560 ± 0.022)% for $H \rightarrow Z\eta_c$ and $H \rightarrow ZJ/\psi$, respectively, and range between (0.140 ± 0.011)% and (3.27 ± 0.06)% for $H \rightarrow Z\eta_c$. The efficiencies are highest for the lowest a mass hypotheses, due to higher probabilities to pass the MLP requirement. The efficiency for $H \rightarrow Z\eta_c$ events to pass the MLP requirement is lower than that of $H \rightarrow ZJ/\psi$ events, as $J/\psi$ decays tend to have a lower charged hadron multiplicity. Using the predicted cross section for inclusive SM Higgs boson production of 55.7−3.9 pb [102], and $B[H \rightarrow Z(a)] = 100\%$, gives expected signal yields of 4260 and 4370 for $H \rightarrow Z\eta_c$ and $H \rightarrow ZJ/\psi$, respectively, and between 1090 and 25600 for $H \rightarrow Z\eta_c$.

A “modified ABCD estimate” of the total background in the SR is derived using four regions: A, defined by 0.0341 < $M$ < 0.0524, expected to contain about 10% of the total background, and 155 < $m_{ll}$ < 175 GeV; B, defined by the $m_{ll}$ requirement of the SR and the $M$ requirement of region A; C, defined by the $M$ requirement of the SR and the $m_{ll}$ requirement of A; and D, which is the SR. An initial data-driven background estimate in the SR is calculated as $D = BC/A$, then MC samples, reweighted to match data, are used to correct this estimate for the 13% correlation between the $m_{ll}$ and $M$ variables. This reweighting is performed in the $p_t$ of the calorimeter jet, the number of ghost-associated tracks and $U_1(0.7)$. This background estimate is 82400 ± 2900 events in the SR, where the uncertainty is due to the limited data and MC sample statistics. The background estimation method is found to be consistent with data within 1.7 times the total statistical and systematic uncertainty in 14 validation regions, defined in regions of the $m_{ll}$ and $M$ variables.

A measure of $\sigma(pp \rightarrow H)B[H \rightarrow Z(a)]$ is extracted for a given signal hypothesis using a maximum-likelihood fit [103] to the number of events observed in the SR. The systematic uncertainties are included in the likelihood fit as nuisance parameters, which modify the signal efficiencies or the simulation-based correction used to calculate the expected background yield. These systematic uncertainties include uncertainties in the signal and background modeling and experimental uncertainties. The sources of modeling uncertainty include the limited MC sample statistics, renormalization scale and choice of MC generator for the signal and background, and a signal uncertainty to account for the extrapolation from gluon-gluon fusion signal samples to the inclusive Higgs boson production cross section. The effects of factorization scale and PDF uncertainties are found to be negligible. The experimental uncertainties considered are due to the luminosity [104], pileup [105], triggers, lepton [81,106,107], and jet [96] reconstruction. The total uncertainty on the extracted signal yield is dominated by the background modeling uncertainties, the largest being due to limited MC sample statistics. The total uncertainty on the background in the SR is 3700 events, where the uncertainty due to the limited data and MC sample statistics is 2900 and the modeling uncertainty is 2300. The data statistical uncertainty corresponds to approximately 8% of the total uncertainty on the extracted signal yield.

The SR contains 82908 data events. This result is compatible with the SM background-only expectation, and the three-body mass distribution is shown in Fig. 2. Upper limits at 95% confidence level (CL) are set on $\sigma(pp \rightarrow H)B[H \rightarrow Z(a)]$ for the various signal hypotheses, using the profile-likelihood test statistic [103] and the CLs technique [108]. The observed (expected) upper limits for the $H \rightarrow Z\eta_c$ and $H \rightarrow ZJ/\psi$ hypotheses are 110 and 100 pb (100±30 and 100±30 pb), respectively, while the upper limits for the $H \rightarrow Z\eta_c$ signal hypotheses are given in Table I. In the absence of systematic uncertainties, these limits would range between 1.9 and 55 pb for the different signal hypotheses. To simplify the interpretation, the upper limits are quoted for $B(a \rightarrow gg) = 100\%$ and $B(a \rightarrow s\bar{s}) = 100\%$. Because of the Yukawa ordering of the decays of Higgs bosons, only decays into gluon and strange quark pairs are considered. The tighter limits for the $a \rightarrow s\bar{s}$ decays are due to a higher MLP selection efficiency. The systematic uncertainties for $a \rightarrow gg$ and $a \rightarrow s\bar{s}$ decay hypotheses are estimated using the inclusive decays as modeled in PYTHIA 8, which is a good approximation due to the dominance of the background modeling.
In conclusion, a search has been performed for Higgs boson decays into a $Z$ boson and either a $\eta_c$ or $J/\psi$ charmonium state, or a light spin-0 boson. No excess is found, and 95% CL upper limits are set on $\sigma(pp \to H)B(H \to Z(a)/a)$, with values of 110 and 100 pb for the $H \to Z\eta_c$ and $H \to ZZJ/\psi$ hypotheses, respectively, and with values in the range $17-340$ pb for the $H \to Za$ signal hypotheses. Assuming the SM prediction for inclusive Higgs boson production, the limits on charmonium decay modes correspond to branching fraction limits in excess of 100%. This is the first direct limit on decays of the observed Higgs boson to light scalars, decaying to light quarks or gluons. Because of the large value of $B(a \to$ hadrons) over the entire 2HDM(+$S$) parameter space, these limits represent tight, direct constraints for low (high) $\tan\beta$ in the type-II and type-III (type-VI) 2HDM + $S$ [109].

[86] ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the center of the detector and the z axis along the beam pipe. The x axis points from the IP to the center of the LHC ring, and the y axis points upward. Cylindrical coordinates (r, φ) are used in the transverse plane, φ being the azimuthal angle around the z axis. The pseudorapidity is defined in terms of the polar angle θ as η = −ln tan(θ/2).
