1. Introduction

Monte Carlo simulations play an important role in the data analysis of neutrino telescopes. Simulations are used to design reconstruction algorithms for neutrino events, as well as to estimate cosmic and atmospheric signals in various physics analyses. GENIE [1] is a neutrino event generator focused mainly on the low-energy range (≤ 5 GeV) and presently valid up to 5 TeV. It is currently used by many experiments working in the neutrino oscillation field e.g. [2–7]. The project’s goal is the development of a reference neutrino interaction Monte Carlo simulation tool whose validity extends to PeV scales.

The gSeaGen code simulates events induced by all flavours of neutrinos and detectable by a neutrino telescope, using GENIE to simulate the neutrino interactions. In particular, it allows electron, muon and tau neutrino events to be generated. Depending on the steering parameters it can produce events from multiple (anti)neutrino flavours within one execution of the program (e.g. \( \nu_e + \bar{\nu}_e \)); simulate charged current (CC) and/or neutral current (NC) interactions; and simulate neutrinos arriving isotropically or from point or extended sources. The code was developed for KM3NeT [8]. Although applicable both to underwater and under-ice neutrino detectors, the code terminology, as well as the description presented in this paper, follow those of underwater detectors.

2. The coordinate system

The coordinates in gSeaGen are Cartesian with the positive z-axis pointing to the local zenith, the positive x-axis pointing north and the positive y-axis as needed to make a right-handed coordinate system. By default, the origin is defined as being the water/rock boundary. To define astrophysical source positions, an associated horizontal coordinate system is defined, with the azimuth measured eastward from the North, as shown in Fig. 1. The relation between the source altitude \( a \) and azimuth \( A \) coordinates and the angles \( \theta \) and \( \phi \), defining the arrival direction of the emitted neutrinos, is then:

\[
\begin{align*}
\theta &= 90^\circ - a \\
\phi &= 360^\circ - A
\end{align*}
\] (1)

3. The detector active volume

The detector active volume is defined as a cylinder, the can, having the bottom bounded at the seabed and surrounding the instrumented volume as sketched in Fig. 2. The user can set the defining the z-level of the can bottom \( Z_{\text{can}}^{\text{min}} \), the z-level of the can top \( Z_{\text{can}}^{\text{max}} \) and the can radius \( R_{\text{can}} \). It is possible to define \( Z_{\text{can}}^{\text{min}} \neq 0 \). In this case, the coordinate system origin is translated along the z-axis in order to bound the can to the bottom at the seabed. With this choice, the user can shift the origin along the z-axis from the default position set at \( z = 0 \).

Presently, the bottom of the can is bounded at the seabed; this constraint will be overcome in the next versions. However, detectors not lying on the rock, as in the case of under-ice telescopes, can be simulated by enlarging the can below the detector.

The can represents the detector horizon to the light emitted by the neutrino-induced particles. All the events leading to Cherenkov radiation in the can, i.e. events interacting inside the
The Cartesian and the associated astronomical horizontal systems as defined in SeaGen. The relation between the source altitude \(a\) and azimuth \(A\) coordinates and the angles \(\theta\) and \(\phi\), defining the arrival direction of the emitted neutrinos is shown.

**Fig. 1.** The Cartesian and the associated astronomical horizontal systems as defined in SeaGen. The relation between the source altitude \(a\) and azimuth \(A\) coordinates and the angles \(\theta\) and \(\phi\), defining the arrival direction of the emitted neutrinos is shown.

**Fig. 2.** Definition of the detector can.

can or producing a muon reaching the can surface, are stored in the output file. The particle tracking inside the can and the Cherenkov light emission are performed in the next steps of the simulation chain by independent programs to study the detector response.

**4. The target media**

Four different neutrino target media are defined: SeaWater, Rock, Mantle and Core. The first two are used to define the interaction volume (see Section 5), while the others enter in the calculation of the transmission probability of neutrinos through the Earth (see Section 7). The default compositions for each target medium are listed in Table 1. The densities for SeaWater and Rock are set to \(\rho_s = 1.04\) g/cm\(^3\) and \(\rho_r = 2.65\) g/cm\(^3\) respectively. For Mantle and Core media, the density profile provided by the Preliminary Reference Earth Model (PREM) [9] is used.

The user can change the composition of all target media and the density for SeaWater and Rock, e.g. to study the systematic uncertainties due to medium compositions and also consider under-ice detectors.

**5. The neutrino interaction volume**

The interaction volume is the volume surrounding the detector in which a neutrino interaction can produce detectable particles. It is defined at runtime and is used to simulate the interaction of all generated neutrinos. The interaction volume is built using the TGeoManager ROOT class [10] and is used to configure the GENIE geometry driver. The interaction volume is defined as a cylinder surrounding the can and is made of sea water and rock, whose composition and density are defined using the target media SeaWater and Rock, respectively.

The size and nature of the interaction volume depends on the topology of the generated neutrino events. In the case of electron neutrino CC interactions and all neutrino flavour NC interactions, a particle shower is produced. Such events, here referred to as *shower-like events*, may be detected only if the neutrino interacts inside the light-sensitive volume. In this case the interaction volume is defined as a cylinder coincident with the can and entirely made of seawater. It is possible to extend the interaction volume below the can by adding a layer of rock with the option -bedrock (see Section 10).

Muons produced in the neutrino interaction may be detected also if the interaction vertex is outside the can. This happens in the case of muon neutrinos interacting in CC, for which the muons are the primary leptons produced by the interaction. For this kind of event, referred to as *track-like event*, the interaction volume is built taking into account the muon maximum range in water and rock, evaluated at the highest simulated neutrino energy. The interaction volume is then a cylinder made of a layer of rock and a layer of seawater, with the separation surface coincident with the sea bottom (see Fig. 3). The volume radius is equal to the can radius plus the muon maximum range in water. The layer of rock has a height equal to the muon maximum range in this medium. If up-going events are not simulated the rock layer height is set to zero. The layer of sea water has a height equal to the can height plus the maximum muon range in water and it cannot exceed the
detector site depth. If down-going events are not simulated, the sea water layer height is set equal to that of the can.

Tau neutrinos interacting in CC do not induce long-track tau events at the present GENIE maximum valid energy of 5 TeV. However, muons could result as product of the tau decay. For this reason when CC tau neutrino interaction events are simulated, the interaction volume is defined on the basis of the muon range as in the case of CC interacting muon neutrinos.

When the GENIE extension to very high energies (up to $10^{10}$ GeV) will be available [11], development of a more sophisticated simulation of long-track tau events will be required.

### 6. Generation of neutrino events

A flux driver class implementing the standard GENIE Flux class [12] has been developed within gSeaGen and used to configure the GENIE event generation driver. The interface generates the neutrino energy and the track information needed to simulate the interaction.

The gSeaGen flux driver is able to generate neutrinos coming from diffuse sources (e.g. atmospheric neutrinos) or from point-like and extended astrophysical sources. The neutrino energy is always generated according to a power law spectrum. However, the code provides for each event a weight that can be used to re-weight the generated neutrino events to the chosen astrophysical or atmospheric neutrino spectrum.

The neutrino generation algorithm implemented in the gSeaGen flux driver is described in this section.

#### 6.1. Generation of the neutrino direction

The generation of the neutrino direction depends on the kind of simulated neutrino flux. In case of diffuse fluxes, the neutrino arrival direction, defined by the $\theta$ and $\phi$ angles, is randomly extracted according to an isotropic distribution and the neutrino direction cosines ($v_x$, $v_y$, $v_z$) are computed according to:

\[
\begin{align*}
  v_x &= -\sin(\theta) \cdot \cos(\phi) \\
  v_y &= -\sin(\theta) \cdot \sin(\phi) \\
  v_z &= -\cos(\theta)
\end{align*}
\]  

(2)

If neutrinos from an astrophysical point-like source are simulated, the direction is generated along the apparent source trajectory in the sky due to the Earth’s rotation. The trajectory is calculated using the source equatorial coordinates (declination $\delta$ and right ascension RA) and the geographic coordinates of the detector, provided by the user.

The local sidereal time (LST) is uniformly extracted between 0 and 24 h and the corresponding source hour angle, HA = RA–RA, is calculated. The code then computes the horizontal coordinates of the source, altitude $\phi$ and azimuth $\theta$, according to:

\[
\begin{align*}
  \tan(\phi) &= \frac{\sin(\delta) \cdot \sin(\lambda) + \cos(\delta) \cdot \cos(\lambda) \cdot \cos(HA)}{\cos(HA) \cdot \sin(\lambda) - \tan(\delta) \cdot \cos(\lambda)} + 180^\circ \\
  \sin(\phi) &= -\cos(\theta)
\end{align*}
\]

(3)

where $\lambda$ is the detector latitude.\(^1\) Source position may be given also in galactic coordinates and the transformation to the equatorial reference system is done by gSeaGen.

As an example, neutrinos coming from the supernova remnant RX J1713.7–3946 direction (RA: 17$^h$ 13$^m$ 33.1, $\delta$: −39° 45' 44") have been simulated. The generated horizontal coordinates at the KM3NeT-ARCA site (latitude: N 36° 17' 48.34", longitude: E 15° 58' 42.25") are plotted in Fig. 4.

Once the source position in the sky is generated, the neutrino arrival direction angles are computed using Eq. (1) and then transformed into the neutrino direction cosines with Eq. (2).

The user also has the possibility to generate the events in a given time interval, simulating neutrinos from transient sources. In this case the modified Julian day (MJD) is uniformly extracted between the two selected dates. The value of the LST at the extracted MJD is then calculated to determine the horizontal coordinates of the source.

Finally, gSeaGen gives the possibility to simulate neutrinos coming from an extended astrophysical source with a small angular radius $R_s$ ($R_s \lesssim 10^\circ$). The generation proceeds as in the case of a point-like source with astronomical coordinates coincident with the extended source centre. Then, the neutrino directions are randomly generated according to a uniform distribution within a disc of radius $R_s$.

For example, the arrival direction of neutrinos coming from RX J1713.7–3946 has been randomised in a circle of $R_s = 0.6^\circ$.

\(^1\) The difference between geographical and geocentric latitudes is not taken into account since the corrections in the coordinates are negligible with respect to the angular resolutions of neutrino telescopes of tenths of a degree. Corrections for parallax are also neglected since they are irrelevant for the distant astrophysical neutrino sources [13].
Fig. 4. Horizontal coordinates of neutrinos coming from the supernova remnant RX J1713.7-3946 direction generated with LST between 0 and 24 h at the KM3NeT-ARCAsite.

Fig. 5. Equatorial coordinates of neutrinos generated from the extended source RX J1713.7-3946 with $R_s = 0.6^\circ$. The red star represents the coordinates of the source.

corresponding to the source extension. The equatorial coordinates of the generated neutrinos are plotted in Fig. 5.

Sources of arbitrary topology can be simulated by re-weighting the flux within the generated disc (see Section 7).

All astronomical algorithms needed in the simulation of astrophysical sources have been implemented in a gSeaGen internal library based on Ref. [13].

6.2. Generation of the neutrino vertex

As in the standard GENIE neutrino flux drivers, the neutrino vertex is generated on a circular surface with radius $R_T$. The generation area is tangent to a sphere of radius $R_L$, centred at the detector can centre (see Fig. 6). The radius $R_L$ is equal to the diagonal of the interaction volume so that the generation area is always outside this volume. The radius of the generation area is:

$$ R_T = D/2 + 100 \text{ m}, $$

where $D$ is the detector diagonal. Using option -$rt$, the user has the possibility to modify the radius of the generation area setting $D$ equal to the interaction volume diagonal or $R_T$ to a given value (see Section 10).

A circular generation area with a fixed radius disfavours particular directions when the detector is strongly asymmetric. Thus, an alternative new method has been developed to spread neutrino vertices within the surface defined by the projection of the can on to the plane perpendicular to the neutrino direction. This increases the number of events at the can by 30% or more, depending on the can shape. When this method is activated (with option -$rt$), the generation area is not constant but depends on the neutrino direction.

6.3. Generation of the neutrino energy

Neutrinos are generated with energy following a power-law spectrum $E^{-X}$, where $X$ is the spectral index input by the user.
gSeaGen gives the possibility to bin the energy spectrum in equal divisions in \( \log_{10}(E) \). The number \( N' \) of incoming neutrinos in each bin, ranging from \( E'_{\text{min}} \) to \( E'_{\text{max}} \), is given by:

\[
N' = N_{\text{tot}} \cdot \frac{\int_{E'_{\text{min}}}^{E'_{\text{max}}} E^{-X} dE}{\int_{E'_{\text{min}}}^{E'_{\text{max}}} E^{-X} dE}, \tag{5}
\]

where \( N_{\text{tot}} \) is the total number of neutrinos in the whole energy range from \( E_{\text{min}} \) to \( E_{\text{max}} \). When muon inducing events are simulated, the interaction volume is scaled according to the maximum muon range in rock and water, calculated at the highest neutrino energy in the bin (see Section 5).

Since interaction probabilities are very small numbers, GENIE scales up the probabilities to reduce the number of trials. This is reflected in the weights of interacting neutrinos as discussed in Section 7. The probability scale is defined as the maximum possible total interaction probability, i.e., the probability at the maximum neutrino energy (corresponding to the maximum cross section) and for the maximum possible neutrino path length in the interaction volume [1]. When the energy range is binned, the interaction probability is scaled up at each bin, increasing the statistics for lower neutrino energies. In this way, the simulation can span different orders of magnitude in energy, as usually required in the simulation of neutrino telescopes.

### 6.4. Neutrino interaction and events at the detector

Once the neutrino energy, position and direction are generated, the neutrino interaction is simulated using the GENIE event generation driver class GMCDriver [1]. If the neutrino interacts inside the can, all particles in the final state are stored in the output file. In the case of CC interaction of muon or tau neutrinos, the interaction could take place outside the can and still produce a visible lepton in the detector. In this case, all induced particles are rejected except the muons produced at a distance from the can lower than the maximum range in water. These muons are propagated and stored in the output file if they reach the can surface.

It is possible to add a layer of rock just below the can using the option “bedrock” (see Section 10). In this case, all particles produced in the interaction are stored in the output file and the rock layer is considered part of the can for their propagation. By default, gSeaGen uses its internal muon propagator code PropaMuon, described in Appendix. Alternatively, it is also possible to use external propagators such as MUSIC [14] and PROPOSAL [15], if enabled at compile-time.

### 7. Computation of the event weight

During the simulation, each event is assigned a weight \( w_{\text{evt}} \) in order to shape the generation to the expected neutrino flux. The event weight is the product of the generation weight \( w_{\text{gen}} \) and of the value of the neutrino energy spectrum \( f(E, \theta, \phi) \):

\[
w_{\text{evt}} = w_{\text{gen}} \cdot f(E, \theta, \phi). \tag{6}\]

The generation weight is:

\[
w_{\text{gen}} = \frac{l_{\nu} \cdot l_{\nu} \cdot T_{\text{gen}} \cdot A_{\text{gen}} \cdot N_{\nu} \cdot E^{X} \cdot P_{\text{scale}} \cdot P_{\text{earth}}(E, \cos \theta)}{N_{\text{tot}}}, \tag{7}\]

where:

- \( l_{\nu} \) is the angular phase space factor, depending on the type of neutrino source:

\[
l_{\nu} = \begin{cases} 
2\pi \cdot ((\cos \theta)_{\text{max}} - (\cos \theta)_{\text{min}}) & \text{for diffuse flux (sr)} \\
1 & \text{for point/extended sources (dimensionless)}
\end{cases}
\]

- \( T_{\text{gen}} \) is the simulated livetime, equal to one year expressed in seconds. In the case of point-like or extended sources for which neutrinos are generated between two dates defined by the user (see Section 6.1), \( T_{\text{gen}} \) is set to the corresponding time interval.

- \( A_{\text{gen}} \) is the area of the generation surface expressed in m². It has the constant value \( \pi R_{\text{Earth}}^2 \) when the generation area is defined as a circle with a fixed radius. When the user activates the generation on the can projection (see Section 6.2), \( A_{\text{gen}} \) depends on the neutrino direction and is calculated for each event by the code.

- \( N_{\nu} \) is the number of generated neutrino types.

- \( E^{X} \) is the reciprocal of the generation spectrum evaluated at the generated neutrino energy.

- \( N_{\text{tot}} \) is the total number of simulated incoming neutrinos.

- \( P_{\text{scale}} \) is the GENIE interaction probability scale [1] (see Section 6.3).

- \( P_{\text{Earth}} \) is the transmission probability through the Earth evaluated as:

\[
P_{\text{Earth}}(E, \cos \theta) = e^{-N_{\text{Earth}} \cdot \sigma(E) \cdot \rho(E)}, \tag{9}\]

where \( \sigma(E) \) is the total CC cross section per nucleon (accounting for the different layer compositions). This ignores the (small) effect of NC interactions, which will reduce the neutrino energy without absorbing it. The tau regeneration is also ignored since it is not relevant at the present neutrino energies and will be implemented in the future when the GENIE extension to very high energies will be available [11]. \( \rho(E) \) is the column depth along the neutrino path inside the Earth up to the interaction vertex. It is computed as the line integral \( \rho(E) = \int_{L} \rho_{\text{Earth}}(r) dr \), where \( L \) is the neutrino path at the angle \( \theta \) and \( \rho_{\text{Earth}}(r) \) is the Earth density profile according to the PREM model [9] (see Table 2). The column depth and the transmission probability for different neutrino energies calculated by gSeaGen are shown in Figs. 7 and 8, respectively.

### 8. Calculation of the systematic weights

The known accuracy of the input simulation parameters can be propagated with GENIE to provide uncertainties related to neutrino interactions. For each input physics quantity \( P \), a systematic parameter \( x_P \) is introduced. Tweaking it modifies the corresponding physics parameter \( P \) as follows:

\[
P \rightarrow P' = P(1 + x_P \cdot \delta P/P), \tag{10}\]

where \( \delta P \) is the estimated standard deviation of \( P \). The calculation of the systematic errors in GENIE is based on an event re-weighting strategy. A description of the full re-weighting scheme is reported in [12].

The evaluation of the systematics has been implemented in gSeaGen, using the GENIE class GEWeight [12]. The implementation accepts single parameters or a list of them as input. In the latter case, the code treats all parameters at the same time and calculates the global systematic weight. If the calculation is activated, the systematic weights \( w_{\text{sys}} \) are written in the output
Table 2
Earth density profile according to the PREM model [9]: the variable $\chi$ is the normalised radius $\chi = r/R_E$, where $r$ is the distance from the Earth centre and $R_E = 6371$ km is the Earth radius. SiteDepth is the detector site depth. The third column indicates the target medium associated to each layer.

Fig. 7. Column depth as a function of the neutrino arrival direction according to the PREM model [9]. The spread visible for downward going neutrinos is due to the range of interaction vertex depths from the same arrival direction.

Fig. 8. Transmission probability through the Earth $P_{\text{Earth}}$ as a function of the neutrino arrival direction and for different neutrino energies.

9. Installing the code

The gSeaGen source code can be downloaded from zenodo.org/record/3715310 [16]. Its compiling requires a Linux-like operating system and some basic tools, such as the gcc compiler suite, make and PERL. A minimal installation of gSeaGen requires only GENIE2 as external package.

A number of environmental variables must be defined:

- GSEAGEN pointing at the top level gSeaGen directory;
- GENIE pointing at the top level GENIE directory;
- ROOTSYS pointing at the top level ROOT directory.

gSeaGen has been written using the GENIE Auk production release series and tested with GENIE version 2.12.10. It is also possible to link gSeaGen with the new Bear release series (GENIE v3.0.0 and later). In this case the GENIE environmental variables for compiling are:

- GENIE pointing at the top level GENIE Generator directory;
- GENIE_REWEIGHT pointing at the top level GENIE Reweight directory.

When the environmental variables are set, a minimal installation of gSeaGen is obtained typing:

```
$ cd $GSEAGEN
$ ./configure
$ make
```

The configuration script allows enabling/disabling features and specifying paths to external libraries such as the MUSIC and PROPOSAL propagators. The command

```
$ ./configure --help
```

lists the configuration options. The configuration script also creates the shell scripts setenv.sh and setenv.csh, helping the user to prepare the environment to run the code.

10. Usage

To set the environment configuration required to run gSeaGen, the setenv script must be executed:

```
$ source $GSEAGEN/setenv.csh (in tcsh or csh shells)
$ source $GSEAGEN/setenv.sh (in bash shell)
```

---

2 The installation of GENIE is described in its user manual [12] and in its web site http://www.genie-mc.org.
The environmental variables required by GENIE and the ROOT version used during the compilation step are also set. Finally, the user can run the code with the following syntax:

```
$ gSeaNuEvGen [OPTIONS]
```

Running the code with the option `-h` (i.e. `$ gSeaNuEvGen -h`), the code writes the list of the available options:

- `a generation_spectral_index [default: 1.4]` Specifies the generation spectral index.
- `b n_of_bins [default: 1]` Specifies the number of energy bins in equal divisions in $\log_{10}(E)$. 
- `bedrock bedrock_height [default: 0]` Specifies the height of the bedrock just below the sea bottom (in metres).
- `c "CAN:Zmin,Zmax,Rad" [default: "CAN:0.000,659.862,309.450"]` Specifies the detector can size where Zmin and Zmax are bottom and top Z coordinates of the can and Rad is its radius in metres. 
- `--coord "UNIT:longitude,latitude" [default: RAD:0.74700,0.10763]` Sets detector site latitude and longitude in radians (UNIT=RAD) or in degrees (UNIT=DEG).
- `--cross-sections XSecName [default: gxspl-FNALsmall.xml]` Inputs the name of an XML file with pre-computed cross-section values used for constructing splines for GENIE.
- `--depth [default: 2475]` Specifies the site depth in metres.
- `--event-generator-list list_name [default: Default]` List of event generators to load. Valid settings are the XML block names appearing in $\$GENIE/config/EventGeneratorListAssembler.xml.
  
  eg. `--event-generator-list CC`  
  eg. `--event-generator-list NC`
- `--f "simul:flux[nu_code],...,"` Specifies the types of neutrinos to be generated and the neutrino fluxes used to weight the events (see Section 11.1 for details).
- `--n n_of_neutrinos` Specifies the number of incoming neutrinos.
- `--o output_event_file_prefix [default: gseagen]` Sets the prefix of the output event file. The output filename is built as: `[prefix][run_number].root`
- `--seed random_number_seed [default: 12345]` Specifies the random seed number.
- `--t min_costheta,max_costheta [default: 0.,1. (up-going neutrinos)]` Specifies the angular range of the neutrino arrival directions.
- `--tune generator_tune [default: G18_02a_00_000]` Specifies the generator tune, required only for GENIE version $\geq$ 3.00.00.
- `-v` Writes the native GENIE output in [prefix][run_number].root

### 11. Input files

#### 11.1. Neutrino flux files

The user can define the type of neutrino and the neutrino fluxes used to weight the events with the option `-f` at run time. This does not affect the energy of the generated neutrinos since the power-law of the generation is controlled by options `-a` and `-e`. The general syntax of option `-f` is:

```
-f "simul:flux,...[nu_code],flux...[nu_code];simul:...",
```

where the tag simul specifies the flux model, flux is the name of the file containing the flux values and nu_code is the neutrino type in the PDG code [17] (12: $\nu_e$, −12: $\bar{\nu}_e$, 14: $\nu_\mu$, −14: $\bar{\nu}_\mu$, 16: $\nu_\tau$, −16: $\bar{\nu}_\tau$).

The neutrino flux can be provided with an ASCII file, containing the value of the neutrino spectrum at different neutrino energies and arrival directions. In order to get a continuously

---

3 Pre-computed cross-sections for GENIE are available on http://www.genie-mc.org.
weighted flux, the code interpolates the tabulated values at the generated neutrino energy and direction. Possible values for the simul tag are BARTOL, FLUKA and HONDA that allow to read directly in the formats available on the web sites of Refs. [18–20], respectively. For example:

- f "BARTOL:f210_3_z.kam_num[14]",
- f "FLUKA:sk_numu02.dat[14]",
- f "HONDA:grn-ally-20-12-solmin.d[14]":

Different neutrino types or neutrinos and anti-neutrinos can be simulated simultaneously, e.g.:

- f "BARTOL:f210_3_z.kam_num[14],f210_3_z.kam_nbm[-14]",
- f "HONDA:grn-ally-20-12-solmin.d[14,-14]":

It is possible to define more than one file for each neutrino code. Fluxes from different files will be added, e.g.:

- f "BARTOL:fmin10_0401z.kam_nue,f210_3_z.kam_num[14]",
- f "BARTOL:f210_3_z.kam_num[14],f210_3_z.kam_nbm[-14]",
- f "FUNC1:1E-5*pow(x,-2)[14]",
- f "[14,-16]",
- f "[12,14]",
- f "[16,-16]".

In this case the code sets by default the irown file. The file should have three columns corresponding to the following items of information:

- log_{10}(E), where E is the muon energy in GeV,
- log_{10}(R_w), where R_w is the range in water in m.w.e.,
- log_{10}(R_w), where R_w is the range in sea water in m.w.e.

The muon energy range in the file must be large enough to cover all possible energies of generated muons, while there are no constraints on the number of rows and on the energy binning. To define the new muon range input file, the user has then to define the environmental variable GMURNGFL pointing to the file with max muon ranges, e.g.:

GMURNGFL = $GSEAGEN$/dat/muon_rmax_music.dat.

11.3. Target medium composition file

To override default target medium compositions defined in Section 4, the user has to define the environmental parameter MEDIACOMP, pointing to the file defining the new compositions. The input file must be in XML format where the root element must be media_comp. The compositions are defined inside the tag param_set. Its attribute media specify the name of the target medium. Possible values for media are: SeaWater, Rock, Mantle and Core. Each chemical element is given through the tag param, where the attribute name indicates the chemical element name and the content defines the value of the mass fraction. The list of elements from which the user can select to define a composition is: Al, Br, C, Ca, Cl, Fe, H, K, Mg, N, Na, Ni, O, S, Si, Ti. The mass number must not appear in the value of the attribute name, since it will be automatically set to the most abundant isotope. For example, the file:

```xml
<media_comp>
  <param_set media="SeaWater">
    <param name="O"> 0.533 </param>
    <param name="H"> 0.1121 </param>
    <param name="Na"> 0.1378 </param>
    <param name="Mg"> 0.0994 </param>
    <param name="S"> 0.0498 </param>
  </param_set>
</media_comp>
```

will re-define the SeaWater and Rock compositions respectively with pure water and standard rock, while default compositions for Mantle and Core will be used. The user has the possibility to set the density value (in g/cm^3) for SeaWater and Rock media, adding the attribute density to the tag param_set. For example it is possible to use the SeaWater medium to simulate ice by writing:

```xml
<media_comp>
  <param_set media="SeaWater" density="0.92">
    <param name="O"> 0.533 </param>
    <param name="H"> 0.1121 </param>
    <param name="S"> 0.0498 </param>
  </param_set>
</media_comp>
```

The attribute density is ignored for Mantle and Core media, for which the PREM density profile is always used. For another example, the user can have a look at the file $GSEAGEN$/dat/MediaComposition.xml, which explicitly defines all the compositions with their default values.

11.4. Astrophysical source info file

To activate the simulation of an astrophysical source, the user has to use the option -point, followed by information about the source. By default, a point-like source is simulated but an angular radius can also be set to simulate an extended circular source. It is possible to input just the source declination (-point DEC:Declination\(^{10}\), with Declination in degrees): the right ascension will be set to zero and the apparent point-like source trajectory will be simulated generating the LST between 0h and 24h. If point/extended mode is activated, only tag FUNC1 for the -f option is available in the present version.
The user also has the possibility to input a file containing information about the source (e.g. 
-point "FILE:AstroSource.xml"), such as the source equatorial or galactic coordinates, the date range in MJD and the source angular radius for an extended source. The input file must be in XML format where the root element is astro_source. Source information is set inside the tag param_set, where its attribute source_name specifies the name of the simulated source. Each piece of information is provided using the tag param, where the attribute name indicates the source parameter and the content defines the corresponding value. For example, giving the following file as input:

```xml
<?xml version="1.0" encoding="ISO-8859-1"?>
<astro_source>
  <param_set source_name="Dec-60">
    <param name="Declination"> -60. </param>
    <param name="RightAscension"> 0. </param>
  </param_set>
</astro_source>
```

is equivalent to running the code with the option

```bash
-PO "DEC: -60"
```

The complete list of all possible parameters is reported in Table 3. For example, the file

```bash
$GSEAGEN/dat/AstroSource.xml
```

defines information for the star Antares and generates events during the whole of 2016.

11.5. Systematic parameter input file

The calculation of the systematic errors related to the neutrino interaction models is activated by defining the environmental variable SYSTLIST. The variable must point at the input file containing the list of physics parameters that can be varied and the associated systematic parameters (see Section 8). The input file is in XML format where the root element must be syst_param. The physics parameters are defined inside the tag param_set which accepts the attribute set_type. Setting set_type="list" defines a list of parameters. In this case, the code treats all parameters simultaneously and will calculate the global systematic weight. Each parameter to be considered for the calculation of the systematic weight is inserted with the tag param, where the attribute name indicates the physics parameter and the content defines the value of the corresponding systematic parameter, e.g.:

```xml
<astro_source>
  <param_set set_type="list">
    <param name="MFP_pi"> +1.0 </param>
    <param name="MFP_N"> -1.0 </param>
  </param_set>
</astro_source>
```

is equivalent to writing:

```xml
<参数_set set_type="list">
  <param name="MFP_pi"> +1.0 </param>
  <param name="MFP_N"> -1.0 </param>
</参数_set>
```

Setting set_type="parameter" defines single physics parameters. In this case, the code will calculate the systematic weights for each parameter, separately. The results will be output in dedicated tags: WSysGEN_ParName, where ParName is the name of the systematic parameter.

As before, each physics parameter is input with the tag param, where the attribute name indicates the parameter name. In this case the content defines the number of the systematic parameter tweaking dial values between -1 and 1. For example, when setting:

```xml
<param_set set_type="parameter">
  <param name="MFP_pi"> 5 </param>
  <param name="MFP_N"> 3 </param>
</param_set>
```

the code will compute the systematic weights for the systematic parameter values -1, -0.5, 0, +0.5, +1 for the physics parameter MFP_pi and for values -1, 0, +1 for MFP_N.

An example can be found in the file

```bash
$GSEAGEN/dat/SystParams.xml
```

for the complete list of the physics parameters considered in GENIE, see table 9.1 of Ref. [12].

12. Output file

The native gSeaGen event output is a ROOT file containing two "trees": Header and Events.

The Header tree reports the general information about the simulation:

- gSeaGenVer (string): gSeaGen version;
- GenieVer (string): GENIE version;
- RunTime (string): running time;
- RunNu (int): run number;
- RandSeed (int): random generator seed;
- EventGeneratorList (string): list of simulated interaction channels;
- InpXSecFile (string): cross-section spline file;
- NTot (double): total number of generated incoming neutrinos;
- EvMin, EvMax (double): generated neutrino energy range (GeV);
- CtMin, CtMax (double): generated neutrino arrival cos \( \theta \) range;
- Alpha (double): generation spectral index;
- NBin (int): number of energy bins;
- Can1, Can2, Can3 (double): \( Z_{min} \), \( Z_{max} \) and \( R_{can} \) of the can (m);
- HRock, HSeaWater, RVol (double): interaction volume: height in rock and water and radius (m);
- SiteDepth (double): site depth (m);
- SiteLatitude, SiteLongitude (double): detector latitude and longitude (rad);
- Agen (double): area of the generation surface (m²);
Table 3
Complete list of input astronomical source parameters. If both equatorial and galactic coordinates are set, the equatorial ones will be used. If both MJDs or dates are set, the MJDs will be used. If an interval time is set, via MJDs or dates, then TGen = (MJDStop-MJDStart)\times10\,000 \ s (1 \ yr as in the diffuse mode).

- **Dx_pl, Dy_pl, Dz_pl (double)**: primary lepton track direction cosines;
- **T_pl (double)**: time of neutrino interaction (ns);
- **NTracks (int)**: final number of particles in the event;
- **Id_tr (int[NTracks])**: particle Id number;
- **E_tr (double[NTracks])**: particle energy (GeV);
- **Pdg_tr (int[NTracks])**: particle PDG code;
- **Vx_tr, Vy_tr, Vz_tr (double[NTracks])**: coordinates of final particle position (m);
- **Dx_tr, Dy_tr, Dz_tr (double[NTracks])**: particle track direction cosines;
- **T_tr (double[NTracks])**: time of passage through the final position with respect to the interaction time (ns);
- **NSysWgt (int)**: number of lists of systematic parameters;
- **WSys (double[NSysWgt])**: systematic weights for each list of parameters, in the same order in which the lists are defined;
- **NSysWgt_ParName (int)**: number of the tweaking dial values between −1 and 1 for the parameter ParName;
- **WSys_ParName (double[NSysWgt_ParName])**: systematic weights for each tweaking dial value for the parameter ParName.

13. Applications

The gSeaGen code has been developed to provide the possibility to use maintained neutrino interaction codes/libraries. The code has been used as a cross-check for GENHEN [21], the reference neutrino simulation code for the ANTARES experiment [22], written in FORTRAN, and presently used also by the KM3NeT Collaboration for the ARCA detector [8] simulation.

As an example, muon neutrinos have been generated up to the present GENIE maximum valid energy of 5 TeV. The spectrum of generated events has been weighted according to the Bartol atmospheric muon flux model [23]. The results are shown in Fig. 9.

GENHEN is not optimised at energies below ∼ 100 GeV and cannot be used to simulate interactions below 10 GeV. Moreover, it does not allow for the evaluation of systematics due to neutrino interaction models. For these reasons, the gSeaGen code was used by the ANTARES Collaboration in the final data analysis to measure atmospheric neutrino oscillation parameters [25].

These limitations of GENHEN at lower energies are especially important for the KM3NeT Collaboration, hence gSeaGen has been chosen as the reference code for the simulation of the ORCA.
Fig. 9. Energy spectrum (top) and angular distribution (bottom) of atmospheric muon neutrinos producing detectable events. Generated events are weighted according to the Bartol atmospheric flux [23]. The simulation was carried out with gSeaGen v6r1 [16] using GENIE version 2.12.10 [24]. Results from the standard neutrino event generator GENHEN [21] are shown for comparison. Note the difference in events per year in the 10–100 GeV range, due to GENHEN being optimised for events with energy above 100 GeV.

detector which is optimised to detect neutrinos of a few GeV and is aiming at measuring the neutrino mass hierarchy. The gSeaGen code was used to optimise the detector geometry and to estimate the expected performances published in the KM3NeT Letter of Intent [8]. At present, the code is used to carry out the Monte Carlo simulations for the ORCA data analysis [26].

Furthermore, both DeepCore and Upgrade detectors, which are the existing and the future infills of the existing IceCube neutrino telescope [27], also aim at measuring neutrino oscillations in the GeV range. These detectors are located in glacial Antarctic ice and sit above a layer of bedrock. While the code default values and naming convention specify an in-water detector, gSeaGen will also be suitable for modelling these experiments, with an adaptation of medium properties.

It is planned to extend the use of gSeaGen to the KM3NeT-ORCA and ANTARES high energy analyses when the GENIE extension at the PeV scale will be available [11]. Finally, gSeaGen can be used for GVD [28], a next-generation neutrino telescope being constructed in Lake Baikal. gSeaGen should be well-suited to generate interactions at energies from a few TeV up to 100 PeV for GVD.

14. Conclusions

The gSeaGen code, written in C++ and based on the GENIE neutrino interaction code, has been developed within the KM3NeT Collaboration. The gSeaGen code generates all flavour neutrino interaction events detectable in a Cherenkov neutrino telescope. It can simulate neutrinos coming from diffuse sources (e.g. atmospheric neutrinos) and from point-like or extended astrophysical sources, according to several neutrino fluxes.

The gSeaGen code provides the possibility of changing the composition and the density of the neutrino target medium surrounding the detector, allowing the study of systematic uncertainties due to medium composition and also considering both under-water and under-ice detectors.

Presently, gSeaGen is the reference code for the simulation of the KM3NeT-ORCA detector, aiming at the study of neutrino physics and optimised to detect neutrinos in the GeV energy range. gSeaGen will be also used in the KM3NeT-ARCA and ANTARES TeV-PeV neutrino searches once the extension of the GENIE code up to the PeV scale will be available.

Appendix. The PropaMuon code

The PropaMuon library is a three-dimensional Monte Carlo code for muon propagation through a generic medium. The code simulates the energy losses and the angular deviations of muons taking into account ionisation and radiative processes (bremsstrahlung, direct electron pair production and nuclear interactions).

The muon energy losses are expressed as the sum of the ionisation and radiative losses:

\[ \frac{dE}{dx} = \left( \frac{dE}{dx} \right)_{\text{ion}} + \left( \frac{dE}{dx} \right)_{\text{rad}}. \]  

(A.1)
The fluctuations associated with the ionisation are small and the energy loss mechanism is treated as continuous. The mean value is evaluated with the Bethe-Bloch formula [17]. PropaMuon can consider any medium composition if ionisation coefficients are provided for each element of which it is made. At present only elements listed in Table 1 are considered.

The radiative energy loss is subdivided into a “soft” part, treated as continuous, if the energy fraction \( v \) transferred from the muon to the photon is below a certain threshold \( (v < v_{\text{cut}}) \), here \( v_{\text{cut}} = 10^{-3} \), and a “hard” part \((v \geq v_{\text{cut}})\) treated stochastically [29].

Given an element with atomic mass \( A \), present in the mixture, the radiative energy loss is:

\[
\frac{d\lambda}{dx}_{\text{rad}} = \frac{d\lambda}{dx}_{\text{soft}} + \frac{d\lambda}{dx}_{\text{hard}}
\]

\[
= \frac{N_A}{A} \int_0^{v_{\text{cut}}} \frac{d\sigma(v,E)}{dv} dv + \frac{N_A}{A} \int_{v_{\text{cut}}}^{1} \frac{d\sigma(v,E)}{dv} dv.
\]

The total energy loss in the medium is evaluated as:

\[
\frac{dE}{dx} = \sum w_i \left( \frac{d\lambda}{dx} \right)_i,
\]

where \((d\lambda/dx)_i\) is the energy loss in the \( i \)th element having a weight fraction \( w_i \).

Total cross section, mean free path and probability for “hard radiation” are:

\[
\sigma_{\text{hard}}(E) = \int_{v_{\text{cut}}}^{1} \frac{d\sigma(v,E)}{dv} dv,
\]

\[
\lambda_{\text{hard}}(E) = \frac{A}{\sigma_{\text{hard}}(E) N_A},
\]

\[
P_{\text{hard}}(E) = \frac{1}{\lambda_{\text{hard}}(E)}.
\]

Differential cross sections for radiative processes are computed using the Petruchkin and Shestakov formula [30] for bremsstrahlung, the Kokoulin and Petruchkin formula [31] for direct electron pair production and the Bezrukov and Bugaev formula for the nuclear interaction [32].

Given a muon with energy \( E \), the code extracts the hard radiation interaction path according to:

\[
P(r) = \frac{1}{\lambda_{\text{hard}}} \exp\left(-\frac{r}{\lambda_{\text{hard}}} \right)
\]

and selects the radiative process considering that:

\[
\lambda_{\text{hard}} = \lambda_{\text{hard}}^{\text{brem}} + \lambda_{\text{hard}}^{\text{pair}} + \lambda_{\text{hard}}^{\text{nucl}}.
\]

Then, the code computes the continuous energy loss (ionisation + soft radiation) and simulates the multiple scattering up to the interaction point. For the multiple scattering, the Lynch and Dahl formula [33] is used.

At this point, the code extracts the fraction \( \nu \) of the energy lost by the muon in the selected “hard radiation” process from a numerical solution of the equation:

\[
P = \int_0^1 \frac{d\nu}{dv} dv.
\]

where \( P \) is a random number between 0 and 1. The muon angular deviation due to the selected “hard radiation” process is simulated following the approximations proposed in Ref. [34].

The entire procedure is then repeated until the muon is at rest or input depth is reached. The muon range simulated with the PropaMuon code in pure water and in standard rock is shown in Fig. A.10. For comparison, the ranges simulated with MUSIC and PROPOSAL and the Continuous Slowing Down Approximation (CSDA) range [35] are also shown.
