Searches for dijet resonances with sub-TeV masses using the ATLAS detector at the Large Hadron Collider can be statistically limited by the bandwidth available to inclusive single-jet triggers, whose data-collection rates at low transverse momentum are much lower than the rate from standard model multijet production. This Letter describes a new search for dijet resonances where this limitation is overcome by recording only the event information calculated by the jet trigger algorithms, thereby allowing much higher event rates with reduced storage needs. The search targets low-mass dijet resonances in the range 450–1800 GeV. The analyzed data set has an integrated luminosity of up to 29.3 fb\(^{-1}\) and was recorded at a center-of-mass energy of 13 TeV. No excesses are found; limits are set on Gaussian-shaped contributions to the dijet mass distribution from new particles and on a model of dark-matter particles with axial-vector couplings to quarks.

DOI: 10.1103/PhysRevLett.121.081801

Introduction.—If new particles beyond those of the standard model (SM) are directly produced in proton-proton (\( pp \)) collisions at the Large Hadron Collider (LHC), they must interact with the constituent partons of the proton, and can therefore also decay into the same partons, resulting in two-jet final states. Quantum chromodynamics (QCD) predicts that dijet events have an invariant mass distribution (\( m_{jj} \)) that falls smoothly, whereas a new state decaying to two partons would emerge as a localized excess in the distribution.

Traditional dijet searches at the LHC focus on the production of heavy particles with masses above 900 GeV \cite{1,2,3}. LHC searches for lighter resonances with small production cross sections have been hampered by restrictions in the data-taking rate of the ATLAS and CMS detectors. Single-jet triggers with a jet \( p_T \) threshold below roughly 380 GeV are prescaled, a procedure whereby only a fraction of the events passing the trigger are recorded; hence, dijet events with an invariant mass below 1 TeV are largely discarded by the trigger system, as indicated in Fig. 1. Therefore, despite the large number of \( pp \) collisions produced by the LHC, traditional ATLAS and CMS searches are less sensitive to dijet resonances below 900 GeV than searches at the SPS and Tevatron colliders \cite{4,5,6,7,8,9}. Alternative trigger strategies to search for low-mass resonances include selecting events with jets recoiling against either an energetic photon or an additional energetic jet \cite{10,11,12}, or selecting events with decays to heavy-flavor jets \cite{13,14}. In these cases, additional features in the events reduce the data-taking rates, reducing the sensitivity to low-mass resonances.

This Letter describes an innovative data-taking approach to access the invariant mass region below 1 TeV; only a reduced set of information from the trigger system is recorded and subsequently analyzed. The Trigger-object Level Analysis (TLA) approach allows jet events to be recorded at a peak rate of up to twice the total rate of events using the standard approach, while using less than 1\% of

![FIG. 1. Comparison between the number of dijet events in the data used by this analysis (black points), the number of events selected by any single-jet trigger (thicker, blue line), and the events selected by single-jet triggers but corrected for the trigger prescale factors (thinner, red line) as a function of the dijet invariant mass (\( m_{jj} \)). The definition of \( y^* \) is \( (y_1 - y_2)/2 \), where \( y_1 \) and \( y_2 \) are the rapidities of the highest- and second-highest \( p_T \) jets.](image-url)
the total trigger bandwidth [15]. This strategy is used in dijet resonance searches in $\sqrt{s} = 8$ and 13 TeV LHC $pp$ collision data by the CMS Collaboration [16,17], and it is used by the LHCb Collaboration (e.g. [18]). The analysis presented here uses 29.3 fb$^{-1}$ of $\sqrt{s} = 13$ TeV $pp$ collision data recorded in 2016 by the ATLAS detector.

**ATLAS detector and data sample.**—The ATLAS detector [19] is a multipurpose detector with a forward-backward symmetric cylindrical geometry and nearly 4$\pi$ coverage in solid angle [20], consisting of tracking detectors, calorimeters, and a muon spectrometer. In the pseudorapidity region $|\eta| < 3.2$, high-granularity lead and liquid-argon (LAr) electromagnetic sampling calorimeters are used. A steel and scintillator hadronic tile calorimeter provides coverage in the range $|\eta| < 1.7$. Hadronic calorimetry in the endcap region, $1.5 < |\eta| < 3.2$, and electromagnetic and hadronic calorimetry in the forward region, $3.1 < |\eta| < 4.9$, are provided by LAr sampling calorimeters. A two-level trigger system is used to select events for offline storage [15]. A first-level (L1) trigger based on dedicated hardware identifies jets from $p_T > 20$ GeV are stored. The stored information includes the four-momentum of each jet and a set of calorimeter variables characterizing the jet [24], such as information about the jet quality and structure. The average size of these events is less than 0.5% of the size of full offline events that contain all detector information. For this analysis, all events containing at least one L1 jet with $E_T > 100$ GeV are selected and recorded, corresponding to a total luminosity of 29.3 fb$^{-1}$. Events containing a L1 jet with $E_T > 75$ GeV are also selected, in a subset of these data corresponding to 3.6 fb$^{-1}$ that were collected at the start of the data-taking period. Events with at least one L1 jet with $E_T > 100$ GeV are therefore included in both data sets.

**Calibration procedure.**—After the events are recorded, the trigger-level jet energy and direction are corrected to those of simulated particle-level jets built from stable particles with a lifetime longer than 10 ps, excluding muons and neutrinos. Before any calibration, the jet $p_T$ response, defined as the $p_T$ ratio of a trigger-level jet to the same jet [25] reconstructed offline (offline jet), is between 0.95 and 1.05 in the $p_T$ range considered by this analysis. Since the energy scale for trigger-level and offline jet are very similar, the trigger-level jet calibration employs the same procedure and constants as derived for offline jets [26], with some modifications to account for the unavailability of tracking information for trigger-level jets.

In the calibration procedure, summarized in Fig. 2, an event-by-event jet-area-based calibration [27] is used to correct for contributions from additional proton-proton interactions (pileup) in the same and neighboring crossings of proton bunches. Then, the simulation-based calibration derived for offline jets is applied to trigger-level jets to correct both jet energy and direction. Next, calorimeter-based variables are used to reduce the dependence on the trigger-level jet flavor and to minimize the impact of energy leakage. Only variables related to the trigger-level jet energy fractions in the electromagnetic and hadronic calorimeters and the minimum number of calorimeter cells containing 90% of the trigger-level jet energy are used here since track-based variables, which are normally used in the offline calibration, are not available. With this correction, the trigger-level jet energy resolution is improved by 8% at jet $p_T$ values of 85 GeV and up to 40% for jet $p_T$ values of 1 TeV relative to the previous calibration step. Next, the calibration corrections that restore the relative calibration between central and forward jets in data and simulation are derived for offline jets and applied to trigger-level jets. After these calibration steps, any residual difference between trigger-level jets and offline jets is accounted for in a dedicated correction, based on the $p_T$ response and derived from data in bins of jet $\eta$ and $p_T$. The size of this correction is on average 1%, with values reaching up to 4% in the endcap regions of the calorimeter.

Finally, an in situ calibration is obtained from the data-to-simulation ratio of the $p_T$ balance between offline jets and well-calibrated objects against which the jets recoil. Three different types of well-calibrated objects are used to span the full $p_T$ range of the jets: Z bosons decaying to electrons or muons, photons, and multijets. A polynomial in $\log(p_T)$ is simultaneously fit to the three input measurements to combine them. The resulting curve is taken as

![FIG. 2. Calibration stages for EM-scale trigger-level jets, each applied to the four-momentum of the jet. MC refers to the simulation.](image-url)
Leading trigger-level jet must have either analysis is similar to the one used in Ref. [3]. Events must ranges from 1% at energy scale uncertainty for trigger-level jets at 200 GeV uncertainty due to the modeling of pileup effects and due to the central and endcap regions (simulation, with additional uncertainties equivalent to the calorimeter noise bursts, beam-induced background, or jet pT distribution that result in deviations from the expected smoothly falling invariant mass spectrum. Any dependence of the final mass spectrum on the parametrization of the jet energy scale calibration is tested by comparing different parametrizations on the data as well as on simulations. The fitted in situ calibration curve is compared to the spline-based smoothing procedure in Fig. 3. After the full calibration procedure, the energy of trigger-level jets is equivalent to that of offline jets to better than 0.05% for invariant masses of 400 GeV and their difference is negligible for invariant masses of 1 TeV.

Energy scale and resolution uncertainties derived for offline jets [26] are applied to trigger-level jets in the signal simulation, with additional uncertainties equivalent to the size of the final trigger-to-offline correction (1%–3%). The uncertainty due to the modeling of pileup effects and due to the jet parton flavor are derived specifically for trigger-level jets and are comparable to those of offline jets. The jet energy scale uncertainty for trigger-level jets at 200 GeV ranges from 1% at |η| < 0.8 to 2% in the region between the central and endcap regions (1.0 < |η| < 1.5).

Event selection.—The dijet event selection for this analysis is similar to the one used in Ref. [3]. Events must contain at least two trigger-level jets with |η| < 2.8. The leading trigger-level jet must have either pT > 185 GeV or pT > 220 GeV for the E_T > 75 GeV and E_T > 100 GeV L1 trigger selections, respectively; this ensures that the L1 triggers are fully efficient. The second leading jet must have a pT > 85 GeV. Events that contain jets induced by calorimeter noise bursts, beam-induced background, or cosmic rays are rejected using the same criteria as in Ref. [24], but omitting the track-based charged fraction selection, which is not available for trigger-level jets. This has a negligible effect for this analysis, since most of these backgrounds are already removed by requiring two central jets, as described below. The efficiency and purity of jets passing the selection are measured with a tag-and-probe method using data events with the full detector information. The trigger-level jet reconstruction efficiency is 100% for jets with pT > 85 GeV. The fraction of trigger-level jets that are not reconstructed and selected offline is below 0.1%.

This analysis searches for a dijet resonance with a mass between 450 and 1800 GeV. Two different selection criteria are used for different but overlapping ranges of the mjj spectrum. To search for resonances with 700 GeV < mjj < 1800 GeV, events are required to have |y^*| < 0.6, where y^* = (y_1 - y_2)/2 and y_1 and y_2 are the rapidities of the highest- and second-highest pT trigger-level jets. To search for lower-mass resonances, with mjj > 450 GeV, events with |y^*| < 0.3 are selected from the smaller data sample requiring a L1 jet with E_T > 75 GeV. The more stringent choice of |y^*| < 0.3 selects higher-pT jets at a given invariant mass and thus provides a mass distribution that is unbiased by the leading-jet selection from mjj = 450 GeV.

Background estimation.—The invariant mass spectrum expected from SM dijet production is predicted to be smooth and falling. Prior dijet searches at various collision energies [7,28–32] have found a variety of simple functional forms to describe this shape; however, given the statistical precision of the data and the wide invariant mass range covered by this search, none of the single, simple functional forms can provide a good description of the data.

The SM background distribution is determined using a sliding-window fit [3], where a fitted functional form is evaluated at the bin at the center of a window, which then slides in one-bin steps along the mjj distribution. The evaluated background estimates evaluated in each bin are then collated to form the final background estimate. The signal selection with |y^*| < 0.6 uses a window size of 19 bins in the mjj spectrum from 531 to 2080 GeV, which spans 34 bins in total. The signal selection with |y^*| < 0.3 uses a window size of 27 bins over a total of 40 bins, in the range 400 < mjj < 2080 GeV. The bin sizes have been chosen according to the simulated invariant mass resolution: \( \sigma_{p_T}/p_T = 10.6/p_T \times 0.27/\sqrt{p_T} \times 0.039 \). The sliding window, however, can not be extended beyond the lower edge of the mjj range used in each signal selection. Therefore, for the first 9 (13) bins in the |y^*| < 0.6 (|y^*| < 0.3) signal selection, which corresponds to one half of the window size, the window is fixed to the lower edge of the spectrum and instead of evaluating the fitted functional form at the window center, it is evaluated for each bin in turn. For invariant masses higher than the mjj range used for the search, the window is allowed to extend...
beyond the range, to 2970 (3490) GeV for the $|y^*| < 0.6$ (0.3) signal selection, and the fit is evaluated at the center of the window.

In each sliding window, three functional forms are fit to the data: a five-parameter function of the form

$$f(x) = p_1(1 - x)p_2x^p_3 + p_4\ln x + p_5\ln x^2,$$

where $p_i$ are free parameters and $x \equiv m_{jj}/\sqrt{s}$; a four-parameter function, which is the same as Eq. (1) but with $p_5 = 0$; and a four-parameter function used by the UA2 Collaboration [28], defined as

$$f(x) = \frac{p_1}{x^{p_2}} e^{-p_3x - p_4x^2}. \tag{2}$$

The function used for each signal selection is the one that yields the best $\chi^2$ over the full fitted $m_{jj}$ range. An alternative function is chosen to evaluate a systematic uncertainty. For the signal selection with $|y^*| < 0.6$, Eq. (1) is used, yielding a $\chi^2$ $p$ value of 0.13, while the alternative function is the four-parameter function with a $\chi^2$ $p$ value of 0.11. For the signal selection with $|y^*| < 0.3$, the four-parameter version of Eq. (1) yields the best $\chi^2$ $p$ value of 0.42 and the alternative function is Eq. (2), with a $\chi^2$ $p$ value of 0.35.

The size of the sliding window is optimized to yield the best $\chi^2$ value for the full $m_{jj}$ range while still being larger than the width of the expected signals and therefore insensitive to potential signal contributions. This latter requirement is checked by including signal models in pseudo-data samples and studying the dependence of the signal sensitivity on different window sizes.

Systematic uncertainties in the estimate of the background used in setting limits include the uncertainty due to the choice of functional form and uncertainties in the fit parameter values. The effect of the choice of functional form is evaluated by comparing the nominal function to the alternative. The uncertainties in the fit parameter values are evaluated using pseudoexperiments, where the pseudodata are drawn from Poisson fluctuations around the nominal background model.

Results and limits.—Figure 4 shows the invariant mass distributions for dijet events in each signal region including the results from the sliding-window background estimates. The $\chi^2$ $p$ value of the overall background is 0.13 for the $|y^*| < 0.6$ signal selection and 0.42 for the $|y^*| < 0.3$ signal selection, indicating the data agrees well with the background estimate. The most discrepant interval identified by the BumpHunter algorithm [33,34] is 889–1007 GeV for events with $|y^*| < 0.6$. Accounting for statistical uncertainties only, the probability of observing a deviation at least as significant as that observed in data, anywhere in this distribution, is 0.44 and corresponds to significance of 0.16$\sigma$. Thus, there is no evidence of any localized excess.

20% of the Gaussian mean mass. Models of new resonances with an intrinsic width much smaller than 5% of its mass should be compared to the results with a width equal to the experimental resolution. For models with a larger width, the limit that best matches their width should be used. More-detailed instructions can be found in Appendix A of Ref. [31].

A Bayesian method is applied to the data and simulation of the signal models at a series of discrete masses to set 95% credibility-level upper limits on the cross section times the mass acceptance [30] for the signals described above. The method uses a constant prior for the signal cross section and Gaussian priors for nuisance parameters corresponding to systematic uncertainties. For both observed and expected limits, the sliding window fit is performed for each value of the mass parameter, adding the tested signal shape with a floating normalization to the functional forms stated above. The expected limits are calculated using pseudoexperiments generated from the fit parameters of those functional forms. The uncertainties on the Z' signal model include the jet energy scale and the luminosity. The impact of the jet energy resolution uncertainty is negligible. For the Gaussian model, a constant jet energy scale uncertainty of 3% is applied in accordance with the measured impact of this uncertainty on the Z' samples. The uncertainty in the integrated luminosity is ±2.2%, derived following a methodology similar to that detailed in Ref. [42]. The systematic uncertainties in the background estimate include the choice of the fit function and the uncertainty in the fit parameter values, as described above.

Figure 5 shows limits on the coupling to quarks, gq, as a function of the mass mZ' for the Z' model. Figure 6 shows limits on a possible Gaussian contribution with a width equal to the detector resolution as a function of the mean mass, mG. In both the Z' and Gaussian models, upper limits for masses from 450 to 700 GeV are derived using the distribution with |y*| < 0.3, which is sensitive to the lower masses. Limits for masses above 700 GeV are derived from the mjj distribution with |y*| < 0.6, except for Gaussian signals with a width of 10% where only the |y*| < 0.3 distribution is used.

The limit results show an upward fluctuation at masses of approximately 1 TeV in the |y*| < 0.6 signal region. This is not seen in Fig. 4; when searching for excesses in the data, a background-only hypothesis is used for the sliding window fit. In the observed and expected limits, the fit includes the signal shape in addition to the background parameterization, and can adapt to local data fluctuations that mimic a signal shape. The |y*| < 0.6 signal region, which uses a smaller sliding-window size, is especially sensitive to the difference in the two approaches. Therefore,
limits were not set on signals with a width of 10% for the $|y^*| < 0.6$ signal region as the signal is too wide for the sliding-window size.

Conclusions.—In conclusion, this analysis searches for resonances with masses between 450 GeV and 1800 GeV in dijet events using trigger-level jets in 29.3 fb$^{-1}$ of $\sqrt{s} = 13$ TeV proton-proton collision data recorded by the ATLAS detector at the LHC. The invariant mass distribution presents no significant local excesses compared to the estimated SM background. This analysis provides 95% credibility-level limits on $Z'$ signals and cross sections for new processes that would produce a Gaussian contribution to the dijet mass distribution. Over much of the mass range, the sensitivity to the coupling to quarks, $g_{q}$, is improved by a factor of 2 or more compared to pre-LHC and $\sqrt{s} = 8$ and 13 TeV ATLAS results, and is comparable to CMS searches at $\sqrt{s} = 8$ and 13 TeV using this technique. Gaussian contributions with effective cross sections times acceptance ranging from approximately 6.5 pb at 450 GeV, to 0.4 pb at 700 GeV, to 0.05 pb at 1800 GeV are excluded.

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.
