Search for dark matter and other new phenomena in events with an energetic jet and large missing transverse momentum using the ATLAS detector

The ATLAS collaboration

E-mail: atlas.publications@cern.ch

ABSTRACT: Results of a search for new phenomena in final states with an energetic jet and large missing transverse momentum are reported. The search uses proton-proton collision data corresponding to an integrated luminosity of 36.1 fb$^{-1}$ at a centre-of-mass energy of 13 TeV collected in 2015 and 2016 with the ATLAS detector at the Large Hadron Collider. Events are required to have at least one jet with a transverse momentum above 250 GeV and no leptons ($e$ or $\mu$). Several signal regions are considered with increasing requirements on the missing transverse momentum above 250 GeV. Good agreement is observed between the number of events in data and Standard Model predictions. The results are translated into exclusion limits in models with pair-produced weakly interacting dark-matter candidates, large extra spatial dimensions, and supersymmetric particles in several compressed scenarios.

KEYWORDS: Hadron-Hadron scattering (experiments)

1 Introduction

This paper presents the results of a search for events containing an energetic jet and large missing transverse momentum $\vec{p}_T^{\text{miss}}$ (with magnitude $E_T^{\text{miss}}$) in a data sample corresponding to a total integrated luminosity of 36.1 fb$^{-1}$. The data were collected by the ATLAS Collaboration at the Large Hadron Collider (LHC) from proton-proton collisions at a centre-of-mass energy ($\sqrt{s}$) of 13 TeV. The final-state monojet signature of at least one energetic jet, $E_T^{\text{miss}} > 250$ GeV, and no leptons ($e$ or $\mu$) constitutes a distinctive
signature for new physics beyond the Standard Model (SM) at colliders. The monojet signature has been extensively studied at the LHC in the context of searches for large extra spatial dimensions (LED), supersymmetry (SUSY), and weakly interacting massive particles (WIMPs) as candidates for dark matter (DM) [1–3]. The results of the analysis are therefore interpreted in terms of each of these models, which are described in the following paragraphs.

A range of astrophysical measurements, such as the rotational speed of stars in galaxies and gravitational lensing, point to the existence of a non-baryonic form of matter [4–6]. The existence of a new, weakly interacting massive particle is often hypothesized [7], as it leads to the correct relic density for non-relativistic matter in the early universe [8] as measured from data from the Planck [9] and WMAP [10] Collaborations, if the mass is between a few GeV and one TeV and if it has electroweak-scale interaction cross sections. WIMPs may be pair-produced at the LHC and when accompanied by a jet of particles, for example from initial-state radiation (ISR), these events produce the signature of a jet and missing transverse momentum.

As with the initial results obtained in this search channel at \(\sqrt{s} = 13\) TeV [1], simplified models are used to interpret the results, providing a framework to characterize the new particles acting as mediators of the interaction between the SM and the dark sector [11–13]. The results from simplified models involving s-channel Feynman diagrams such as the one shown in figure 1(a) are comparable to those previously obtained [14] by using an effective-field-theory approach [15] when the mediator mass considered is above 10 TeV [16].

Results are presented for DM models where Dirac fermion WIMPs (\(\chi\)) are pair-produced from quarks via s-channel exchange of a spin-1 mediator particle (\(Z_A\)) with axial-vector couplings, a spin-1 mediator particle (\(Z_V\)) with vector couplings, or a spin-0 pseudoscalar (\(Z_P\)). These models are defined by four free parameters: the WIMP mass (\(m_\chi\)); the mediator mass (\(m_{Z_A}\), \(m_{Z_V}\) or \(m_{Z_P}\), depending on the model); the flavour-universal coupling to quarks (\(g_q\)), where all three quark generations are included; and the coupling of the mediator to WIMPs (\(g_\chi\)). Couplings to other SM particles are not considered. In each case, a minimal mediator width is defined, as detailed in refs. [12, 13], which in the case of the axial-vector mediator takes the form:

\[
\Gamma(m_{Z_A})_{\text{min}} = \frac{g_\chi^2 m_{Z_A}}{12\pi} \beta_\chi^3 \theta(m_{Z_A} - 2m_\chi) + \sum_q \frac{3g_q^2 m_{Z_A}}{12\pi} \beta_q^3 \theta(m_{Z_A} - 2m_q),
\]

where \(\theta(x)\) denotes the Heaviside step function and \(\beta_f = \sqrt{1 - 4m_f^2/m_{Z_A}^2}\) is the velocity in the mediator rest frame of fermion \(f\) (either \(\chi\) or \(q\)) with mass \(m_f\). The quark sum runs over all flavours. The monojet signature in this model emerges from initial-state radiation of a gluon as shown in figure 1(a).

Results are also presented for a DM model in which WIMPs are produced via the exchange of a coloured scalar mediator, which is assumed to couple as a colour-triplet, SU(2) doublet to the left-handed quarks [17–19]. The model contains a variety of new production mechanisms such as the production of WIMP pairs via \(u\)- and \(t\)-channel diagrams with direct couplings of dark matter and SM particles or even s-channel exchange of two
mediators, leading to a different phenomenology. A set of representative diagrams relevant for a monojet final state are collected in figures 1(b)–1(d). A model with simplified assumptions is defined by the following three parameters: $m_\chi$, a single mediator mass ($m_\eta$), and a flavour-universal coupling to quarks and WIMPs ($g_{q\chi} \equiv g$). The mediator is also assumed to couple only to the first two generations of quarks, with minimal decay widths of the form:

$$\Gamma(\eta)_{\text{min}} = \frac{g^2}{16\pi m_\eta^2} \left(m_\eta^2 - m_q^2 - m_\chi^2\right) \sqrt{(m_\eta^2 - (m_q + m_\chi)^2) \left(m_\eta^2 - (m_q - m_\chi)^2\right)},$$

where, to ensure that the DM particle is stable and the mediator width is always defined, $m_\chi^2 + m_q^2 < m_\eta^2$ and $4m_\chi^2/m_\eta^2 < (1 - m_q^2/m_\eta^2 + m_\chi^2/m_\eta^2)^2$ are required.

Supersymmetry is a theory of physics beyond the SM which naturally solves the hierarchy problem and provides candidates for dark matter [20–28]. SUSY introduces a new supersymmetric partner (sparticle) for each particle in the SM. Specifically, a new scalar

Figure 1. (a) Diagram for the pair-production of weakly interacting massive particles $\chi$, with a mediator $Z_A$ with axial-vector couplings exchanged in the $s$-channel. (b)(c)(d) Example of diagrams for the pair-production of weakly interacting massive particles $\chi$ via a coloured scalar mediator $\eta$. (e) A generic diagram for the pair-production of squarks with the decay mode $\tilde{q} \rightarrow q + \tilde{\chi}^0_1$. The presence of a gluon from initial-state radiation resulting in a jet is indicated for illustration purposes.
field is associated with each left- or right-handed quark state. Two squark mass eigenstates \( \tilde{q}_1 \) and \( \tilde{q}_2 \) result from the mixing of the scalar fields for a particular flavour. Naturalness arguments suggest that the third-generation squarks should be light, with masses below about 1 TeV [29]. In addition, many SUSY scenarios have a significant mass difference between the two eigenstates in the bottom-squark (sbottom) and top-squark (stop) sectors, which leads to light sbottom \( \tilde{b}_1 \) and stop \( \tilde{t}_1 \) masses. In supersymmetric extensions of the SM that assume R-parity conservation [30–34], sparticles are produced in pairs and the lightest supersymmetric particle (LSP) is stable. The LSP is assumed to be the lightest neutralino \( \chi^0_1 \).

The results are interpreted in terms of searches for squark production using simplified models in scenarios for which the mass difference \( \Delta m \equiv m_{\tilde{q}} - m_{\chi^0_1} \) is small (compressed-mass scenario). Four such scenarios with compressed mass spectra are considered: stop-pair production, where the stop decays into a charm quark and the LSP (\( \tilde{t}_1 \to c + \chi^0_1 \)), stop-pair production in the four-body decay mode \( \tilde{t}_1 \to b + f f' + \chi^0_1 \), sbottom-pair production with \( \tilde{b}_1 \to b + \chi^0_1 \), and squark-pair production with \( \tilde{q} \to q + \chi^0_1 \) (\( q = u, d, c, s \)). For relatively small \( \Delta m \) (\( \lesssim 25 \) GeV), both the transverse momenta of the quark jets and the \( E_T^{miss} \) in the final state are small, making it difficult to fully reconstruct the signal given the kinematic thresholds for reconstruction. The presence of jets from ISR is thus used to identify signal events (see figure 1(e)). In this case, the squark-pair system is boosted, leading to larger \( E_T^{miss} \).

The final model considered is that of extra spatial dimensions, the existence of which has been postulated to explain the large difference between the electroweak unification scale at \( O(10^2) \) GeV and the Planck scale \( M_{pl} \) at \( O(10^{19}) \) GeV. In the Arkani-Hamed, Dimopoulos, and Dvali (ADD) model of LED [35], the presence of \( n \) extra spatial dimensions of size \( R \) leads to a fundamental Planck scale in \( 4 + n \) dimensions given by \( M_{pl}^2 \sim M_D^{2+n} R^n \), where \( M_D \) is the fundamental scale of the \( 4 + n \)-dimensional theory. Motivation for the theory comes from the possibility that \( M_D \) is of order 1 TeV, a scale accessible at the LHC. In this model, SM particles and gauge interactions are confined to the usual \( 3+1 \) space-time dimensions, whereas gravity is free to propagate through the entire multidimensional space, which effectively dilutes its perceived strength. The extra spatial dimensions are compactified, resulting in a Kaluza-Klein tower of massive graviton modes (KK graviton). If produced in high-energy proton-proton collisions, a KK graviton escaping into the extra dimensions can be inferred from \( E_T^{miss} \), and can lead to a monojet event signature.

The paper is organized as follows. The ATLAS detector is described in the next section. Section 3 provides details of the Monte Carlo simulations used in the analysis for background and signal processes. Section 4 discusses the reconstruction and identification of jets, leptons, and missing transverse momentum, while section 5 describes the event selection. The estimation of background contributions and the study of systematic uncertainties are discussed in sections 6 and 7. The results are presented in section 8 and are interpreted in terms of limits in models of WIMP-pair production, ADD, and SUSY in compressed scenarios. Finally, section 9 is devoted to the conclusions.
2 ATLAS detector

The ATLAS detector [36] covers almost the whole solid angle\(^1\) around the collision point with layers of tracking detectors, calorimeters and muon chambers. The ATLAS inner detector covers the pseudorapidity range \(|\eta| < 2.5\). It consists of a silicon pixel detector, a silicon microstrip detector, and a straw-tube tracker that also measures transition radiation for particle identification, all immersed in a 2 T axial magnetic field produced by a solenoid. During the first LHC long shutdown, a new tracking layer, known as the insertable B-Layer [37], was added just outside a narrower beam pipe at a radius of 33 mm.

High-granularity lead/liquid-argon (LAr) electromagnetic sampling calorimeters cover the pseudorapidity range \(|\eta| < 3.2\). Hadronic calorimetry in the range \(|\eta| < 1.7\) is provided by a steel/scintillator-tile calorimeter, consisting of a large barrel and two smaller extended barrel cylinders, one on either side of the central barrel. In the endcaps (\(|\eta| > 1.5\)), copper/LAr and tungsten/LAr hadronic calorimeters match the outer \(|\eta|\) limits of the endcap electromagnetic calorimeters. The LAr forward calorimeters provide both the electromagnetic and hadronic energy measurements, and extend the coverage to \(|\eta| < 4.9\).

The muon spectrometer measures the deflection of muons in the magnetic field provided by large superconducting air-core toroidal magnets in the pseudorapidity range \(|\eta| < 2.7\), instrumented with separate trigger and high-precision tracking chambers. Over most of the \(\eta\) range, a measurement of the track coordinates in the bending direction of the magnetic field is provided by monitored drift tubes. Cathode strip chambers with higher granularity are used in the innermost plane over \(2.0 < |\eta| < 2.7\). The muon fast trigger detectors cover the pseudorapidity range \(|\eta| < 2.4\) and provide a measurement of the coordinate in the non-bending plane.

The data were collected using an online two-level trigger system [38] that selects events of interest and reduces the event rate from an average of 33 MHz to about 1 kHz for recording and offline processing.

3 Monte Carlo simulation

Monte Carlo (MC) simulated event samples are used to compute detector acceptance and reconstruction efficiencies, determine signal and background contributions, and estimate systematic uncertainties in the final results. Samples are processed with the full ATLAS detector simulation [39] based on GEANT4 [40]. Simulated events are then reconstructed and analysed with the same analysis chain as for the data, using the same trigger and event selection criteria. The effects of multiple proton-proton interactions in the same or neighbouring bunch-crossings (pile-up) are taken into account by overlaying simulated minimum-bias events from PYTHIA 8.205 [41] onto the hard-scattering process, distributed according to the frequency in data.

\(^1\) ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the centre of the detector and the \(z\)-axis along the beam pipe. The \(x\)-axis points from the IP to the centre of the LHC ring, and the \(y\)-axis points upward. Cylindrical coordinates \((r, \phi)\) are used in the transverse plane, \(\phi\) being the azimuthal angle around the \(z\)-axis. The pseudorapidity is defined in terms of the polar angle \(\theta\) as \(\eta = -\ln\tan(\theta/2)\).
3.1 Signal simulation

WIMP s-channel signal samples are simulated in Powheg-Box v2 [42–44] (revision 3049) using two implementations of simplified models, introduced in ref. [45]. The DMV model of WIMP-pair production is used for s-channel spin-1 axial-vector or vector mediator exchange at next-to-leading order (NLO) in the strong coupling, and the DMS_tloop model is used for WIMP-pair production with the s-channel spin-0 pseudoscalar mediator exchange with the full quark-loop calculation at leading order (LO) [46]. Renormalization and factorization scales are set to $H_T/2$ on an event-by-event basis, where $H_T = \sqrt{m_{\chi\chi}^2 + p_{T,j1}^2 + p_{T,j1}^2}$ is defined by the invariant mass of the WIMP pair ($m_{\chi\chi}$) and the transverse momentum of the highest-$p_T$ parton-level jet ($p_{T,j1}$). The mediator propagator is described by a Breit-Wigner distribution. Events are generated using the NNPDF30 [47] parton distribution functions (PDFs) and interfaced to Pythia 8.205 with the A14 set of tuned parameters (tune) [48] for parton showering, hadronization and the underlying event. Couplings of the mediator to WIMP particles and those of the SM quarks are set to $g_X = 1$ and $g_q = 1/4$ for the DMV model whereas both couplings are set to one in the case of the DMS_tloop model. A grid of samples is produced for WIMP masses ranging from 1 GeV to 1 TeV and mediator masses between 10 GeV and 10 TeV.

Samples for DM production in the coloured scalar mediator model are generated with MG5_aMC@NLO v2.3.3 [49] at LO using NNPDF23LO [50] PDFs and interfaced to Pythia 8.186 with the A14 tune for modelling of parton showering, hadronization and the underlying event. The generation of the different subprocesses is performed following a procedure outlined in ref. [18]. Specifically, the generation is split between DM production with an off-shell mediator and on-shell mediator production followed by decay, and the associated production of up to two partons in the final state is included. As already mentioned, only diagrams involving the first two quark generations are considered and processes with electroweak bosons are suppressed. The matching between MadGraph and Pythia is performed following the CKKW-L prescription [51]. The parton matching scale is set to $m_q/8$, where $m_q$ denotes the mass of the mediator, in the case of mediator-pair production, and to 30 GeV otherwise. This particular choice of matching scales optimizes the generation of the samples in the full phase space, and minimizes the impact from scale variations on the shape of the predicted kinematic distributions. The coupling is set to $g = 1$, and a grid of samples is produced for WIMP masses ranging from 1 GeV to 1 TeV and mediator masses between 10 GeV and 2.5 TeV.

SUSY signals for stop-pair production are generated with MG5_aMC@NLO v2.2.3 and interfaced to Pythia 8.186 with the A14 tune for modelling of the squark decay, parton showering, hadronization, and the underlying event. The PDF set used for the generation is NNPDF23LO, and the renormalization and factorization scales are set to $\mu = \sum_i \sqrt{m_i^2 + p_{T,i}^2}$, where the sum runs over all final-state particles from the hard-scatter process. The matrix-element calculation is performed at tree level, and includes the emission of up to two additional partons. Matching to parton-shower calculations is accomplished by the CKKW-L prescription, with a matching scale set to one quarter of the pair-produced superpartner mass. Signal cross sections are calculated at NLO in the strong cou-
pling constant, adding the resummation of soft-gluon emission at next-to-leading-logarithm (NLO+NLL) accuracy [52–54]. The nominal cross section and its uncertainty are taken from an envelope of cross-section predictions using different PDF sets and factorization and renormalization scales, as described in ref. [55]. Simulated samples are produced with squark masses in the range between 250 GeV and 700 GeV, and squark-neutralino mass differences $\Delta m$ varying between 5 GeV and 25 GeV.

Simulated samples for the ADD LED model with different numbers of extra dimensions in the range $n = 2–6$ and a fundamental scale $M_D$ in the range 3.0–5.3 TeV are generated using PYTHIA 8.205 with NNPDF23LO PDFs. The renormalization scale is set to the geometric mean of the squared transverse masses of the two produced particles, $\sqrt{(p^2_{T,G} + m^2_G)(p^2_{T,p} + m^2_p)}$, where $p_{T,G}$ and $m_G$ ($p_{T,p}$ and $m_p$) denote, respectively, the mass and the transverse momentum of the KK graviton (parton) in the final state. The factorization scale is set to the minimum transverse mass, $\sqrt{p^2_T + m^2}$, of the KK graviton and the parton.

3.2 Background simulation

After applying the selection described in section 5, the primary SM background contributing to monojet event signatures is $Z(\to \nu\bar{\nu})$+jets. There are also significant contributions from $W$+jets events, primarily from $W(\to \tau\nu)$+jets. Small contributions are expected from $Z/\gamma^*(\to \ell^+\ell^-)$+jets ($\ell = e, \mu, \tau$), multijet, $t\bar{t}$, single-top, and diboson ($WW, WZ, ZZ$) processes. Contributions from top-quark production associated with additional vector bosons ($t\bar{t}+W$, $t\bar{t}+Z$, or $t+Z+q/b$ processes) are negligible and not considered in this analysis.

Events containing $W$ or $Z$ bosons with associated jets are simulated using the SHERPA 2.2.1 [56] event generator. Matrix elements (ME) are calculated for up to two partons at NLO and four partons at LO using OpenLoops [57] and Comix [58], and merged with the SHERPA parton shower (PS) [59] using the ME+PS@NLO prescription [60]. The NNPDF3.0NNLO [47] PDF set is used in conjunction with a dedicated parton-shower tuning developed by the authors of SHERPA. The MC predictions are initially normalized to next-to-next-to-leading-order (NNLO) perturbative QCD (pQCD) predictions according to DYNNLO [61, 62] using the MSTW2008 90% CL NNLO PDF set [63].

The $W$+jets and $Z$+jets MC predictions are reweighted to account for higher-order QCD and electroweak corrections as described in ref. [64], where parton-level predictions for $W/Z$+jets production, including NLO QCD corrections and NLO electroweak corrections supplemented by Sudakov logarithms at two loops, are provided as a function of the vector-boson $p_T$, improving the description of the measured $Z$-boson $p_T$ distribution [65]. The predictions are provided separately for the different $W$+jets and $Z$+jets processes together with the means for a proper estimation of theoretical uncertainties and their correlations (see section 7). The reweighting procedure takes into account the difference between the QCD NLO predictions as included already in SHERPA and as provided by the parton-level calculations.

For the generation of $t\bar{t}$ and single top quarks in the $Wt$-channel and $s$-channel, the POWHEG-BOX v2 [66] event generator is used with CT10 [67] PDFs. Electroweak $t$-channel
single-top-quark events are generated using the \textsc{Powheg-Box} v1 event generator. This event generator uses the four-flavour scheme to calculate NLO matrix elements, with the CT10 four-flavour PDF set. The parton shower, hadronization, and underlying event are simulated using \textsc{Pythia} 8.205 with the A14 tune. The top-quark mass is set to 172.5 GeV. The \textsc{EvtGen} v1.2.0 program \cite{68} is used to model the decays of the bottom and charm hadrons. Alternative samples are generated using \textsc{MadGraph5\_aMC\_@\_NLO} (v2.2.1) \cite{49} interfaced to \textsc{Herwig++} (v2.7.1) \cite{69} in order to estimate the effects of the choice of matrix-element event generator and parton-shower algorithm.

Diboson samples (WW, WZ, and ZZ production) are generated using either \textsc{Sherpa} 2.2.1 or \textsc{Sherpa} 2.1.1 with NNPDF3.0NNLO or CT10nlo PDFs, respectively, and are normalized to NLO pQCD predictions \cite{70}. Diboson samples are also generated using \textsc{Powheg-Box} \cite{43} interfaced to \textsc{Pythia} 8.186 and using CT10 PDFs for studies of systematic uncertainties.

4 Event reconstruction

Jets are reconstructed from energy deposits in the calorimeters using the anti-$k_t$ jet algorithm \cite{71,72} with the radius parameter (in $y$-$\phi$ space) set to 0.4. The measured jet transverse momentum is corrected for detector effects by weighting energy deposits arising from electromagnetic and hadronic showers differently. In addition, jets are corrected for contributions from pile-up, as described in ref. \cite{73}. Jets with $p_T > 20$ GeV and $|\eta| < 2.8$ are considered in the analysis. Track-based variables to suppress pile-up jets have been developed, and a combination of two such variables, called the jet-vertex tagger \cite{74}, is constructed. In order to remove jets originating from pile-up collisions, for central jets ($|\eta| < 2.4$) with $p_T < 50$ GeV a significant fraction of the tracks associated with each jet must have an origin compatible with the primary vertex, as defined by the jet-vertex tagger.

Jets with $p_T > 30$ GeV and $|\eta| < 2.5$ are identified as $b$-jets if tagged by a multivariate algorithm which uses information on the impact parameters of inner-detector tracks matched to the jet, the presence of displaced secondary vertices, and the reconstructed flight paths of $b$- and $c$-hadrons inside the jet \cite{75,76}. A 60\% efficient $b$-tagging working point, as determined in a simulated sample of $t\bar{t}$ events, is chosen. This corresponds to a rejection factor of approximately 1500, 35 and 180 for light-quark and gluon jets, $c$-jets, and $\tau$-leptons decaying hadronically, respectively.

The presence of electrons or muons in the final state is used in the analysis to define control samples and to reject background contributions in the signal regions (see sections 5 and 6).

Electrons are found by combining energy deposits in the calorimeter with tracks found in the inner detector, and are initially required to have $p_T > 20$ GeV and $|\eta| < 2.47$, to satisfy the ‘Loose’ electron shower shape and track selection criteria described in refs. \cite{77}, and must also be isolated. The latter uses track-based isolation requirements with an efficiency of about 99\%, as determined using \textsc{Z}/$\gamma^*$(→ $e^+e^-$) data. Overlaps between identified electrons and jets with $p_T > 30$ GeV in the final state are resolved. Jets are discarded if they are not $b$-tagged and their separation $\Delta R = \sqrt{(\Delta \eta)^2 + (\Delta \phi)^2}$ from an
identified electron is less than 0.2. Otherwise, the electron is removed as it most likely originates from a semileptonic $b$-hadron decay. The electrons separated by $\Delta R$ between 0.2 and 0.4 from any remaining jet are removed.

Muon candidates are formed by combining information from the muon spectrometer and inner tracking detectors. They are required to pass ‘Medium’ identification requirements, as described in ref. [78], and to have $p_T > 10$ GeV and $|\eta| < 2.5$. Jets with $p_T > 30$ GeV and fewer than three tracks with $p_T > 0.5$ GeV associated with them are discarded if their separation $\Delta R$ from an identified muon is less than 0.4. The muon is discarded if it is matched to a jet with $p_T > 30$ GeV that has at least three tracks associated with it.

The $E_T^{\text{miss}}$ value is reconstructed using all energy deposits in the calorimeter up to pseudorapidity $|\eta| = 4.9$. Clusters associated with either electrons, photons or jets with $p_T > 20$ GeV make use of the corresponding calibrations. Softer jets and clusters not associated with electrons, photons or jets are calibrated using tracking information [79]. As discussed below, in this analysis the missing transverse momentum is not corrected for the presence of muons in the final state.

5 Event selection

The data sample considered corresponds to a total integrated luminosity of 36.1 fb$^{-1}$, and was collected in 2015 and 2016. The uncertainty in the combined 2015+2016 integrated luminosity is 3.2%. It is derived, following a methodology similar to that detailed in ref. [80], from a calibration of the luminosity scale using $x$–$y$ beam-separation scans performed in August 2015 and May 2016. The data were collected using a trigger that selects events with $E_T^{\text{miss}}$ above 90 GeV, as computed from calorimetry information at the final stage of the two-level trigger system. After analysis selections, the trigger was measured to be fully efficient for events with $E_T^{\text{miss}} > 250$ GeV, as determined using a data sample with muons in the final state. Events are required to have at least one reconstructed primary vertex consistent with the beamspot envelope and that contains at least two associated tracks of $p_T > 0.4$ GeV. When more than one such vertex is found, the vertex with the largest summed $p_T^2$ of the associated tracks is chosen. Events having identified muons with $p_T > 10$ GeV or electrons with $p_T > 20$ GeV in the final state are vetoed.

Events are selected with $E_T^{\text{miss}} > 250$ GeV, a leading jet with $p_T,j_1 > 250$ GeV and $|\eta| < 2.4$, and a maximum of four jets with $p_T > 30$ GeV and $|\eta| < 2.8$. Separation in the azimuthal angle of $\Delta \phi(jet, \vec{p}_T^{\text{miss}}) > 0.4$ between the missing transverse momentum direction and each selected jet is required to reduce the multijet background contribution, where a large $E_T^{\text{miss}}$ can originate from jet energy mismeasurement.

Jet quality criteria [81] are imposed, which involve selections based on quantities such as the pulse shape of the energy depositions in the cells of the calorimeters, electromagnetic fraction in the calorimeter, calorimeter sampling fraction, and the charged-particle fraction.$^2$ Loose selection criteria are applied to all jets with $p_T > 30$ GeV and $|\eta| < 2.8$, which remove anomalous energy depositions due to coherent noise and electronic noise bursts in

$^2$The charged-particle fraction is defined as $f_{ch} = \sum p_{\text{track,jet}}^T / p_T^\text{jet}$, where $\sum p_{\text{track,jet}}^T$ is the scalar sum
Table 1. Inclusive (IM1–IM10) and exclusive (EM1–EM10) signal regions with increasing $E_{\text{miss}}$ thresholds from 250 GeV to 1000 GeV. In the case of IM10 and EM10, both signal regions contain the same selected events in data. In the case of the IM10 signal region, the background predictions are computed considering only data and simulated events with $E_{\text{miss}} > 1$ TeV, whereas the EM10 background prediction is obtained from fitting the full $E_{\text{T}}$ shape in data and simulation, as described in section 6.

the calorimeter [82]. Events with any jet not satisfying the loose criteria, as described in ref. [81], are discarded.

Non-collision backgrounds, for example energy depositions in the calorimeters due to muons of beam-induced or cosmic-ray origin, are suppressed by imposing tight selection criteria on the leading jet and the ratio of the jet charged-particle fraction to the calorimeter sampling fraction, $f_{\text{ch}}/f_{\text{max}}$, is required to be larger than 0.1. These requirements have a negligible effect on the signal efficiency.

The analysis uses two sets of signal regions, with inclusive and exclusive $E_{\text{T}}$ selections, where the regions are defined with increasing $E_{\text{T}}$ thresholds from 250 GeV to 1000 GeV (table 1). The inclusive selections are used for a model-independent search for new physics, and the exclusive selections are used for the interpretation of the results within different models of new physics.

6 Background estimation

The $W+$jets, $Z+$jets, and top-quark-related backgrounds are constrained using MC event samples normalized with data in selected control regions. By construction, there is no overlap between events in the signal and the different control regions. The control regions are defined using the same requirements for $E_{\text{T}}$, leading-jet $p_T$, event topologies, and jet vetoes as in the signal regions, such that no extrapolation in $E_{\text{T}}$ or jet $p_T$ is needed from control to signal regions. The normalization factors are extracted simultaneously using a global fit that includes systematic uncertainties, to properly take into account correlations.

Different control samples are used to help constrain the yields of the $W+$jets and $Z+$jets background processes in the signal regions. This includes $W(\rightarrow \mu\nu)+$jets, $W(\rightarrow e\nu)+$jets, and $Z/\gamma^*(\rightarrow \mu^+\mu^-)+$jets control samples, enriched in $W(\rightarrow \mu\nu)+$jets, $W(\rightarrow e\nu)+$jets, and $Z/\gamma^*(\rightarrow \mu^+\mu^-)+$jets background processes, respectively. The dominant $Z(\rightarrow \nu\bar{\nu})+$jets and $W(\rightarrow \tau\nu)+$jets background contributions are constrained in the fit by using both $W+$jets control regions and the $Z/\gamma^*(\rightarrow \mu^+\mu^-)+$jets control region. As of the transverse momenta of tracks associated with the primary vertex within a cone of radius $\Delta R = 0.4$ around the jet axis, and $p_T^{\text{jet}}$ is the transverse momentum of the jet as determined from calorimetric measurements.

$^3$The variable $f_{\text{max}}$ denotes the maximum fraction of the jet energy collected by a single calorimeter layer.
discussed in section 6.4, this translates into a reduced uncertainty in the estimation of the main irreducible background contribution, due to a partial cancelling out of systematic uncertainties and the superior statistical power of the $W$+jets control sample in data, compared to that of the $Z/\gamma^* \rightarrow \mu^+\mu^-$+jets control sample. A small $Z/\gamma^* \rightarrow e^+e^-$+jets and $Z/\gamma^* \rightarrow \tau^+\tau^-$+jets background contribution is also constrained via the $W$+jets and $Z/\gamma^* \rightarrow \mu^+\mu^-$+jets control samples.\footnote{The use of an additional $Z/\gamma^* \rightarrow e^+e^-$+jets control sample to help constrain the $Z/\gamma^* \rightarrow e^+e^-$+jets and $Z \rightarrow \nu\bar{\nu}$+jets background contributions leads to an insignificant improvement in the background determination [1].}

Finally, a top control sample constrains top-quark-related background processes. The remaining SM backgrounds from diboson processes are determined using MC simulated samples, while the multijet background contribution is extracted from data. The contributions from non-collision backgrounds are estimated in data using the beam-induced background identification techniques described in ref. [82].

In the following subsections, details of the definition of the $W=Z$+jets and top control regions, and of the data-driven determination of the multijet and beam-induced backgrounds are given. This is followed by a description of the background fits.

### 6.1 Control samples

A $W(\rightarrow \mu\nu)$+jets control sample is selected by requiring a muon consistent with originating from the primary vertex with $p_T > 10$ GeV, and transverse mass in the range $30 < m_T < 100$ GeV. The transverse mass $m_T = \sqrt{2p_T^\ell p_T^\nu [1 - \cos(\phi^\ell - \phi^\nu)]}$ is defined by the lepton and neutrino transverse momenta, where the $(x, y)$ components of the neutrino momentum are taken to be the same as the corresponding $p_T^{miss}$ components. Events with identified electrons in the final state are vetoed. In addition, events with an identified $b$-jet in the final state are vetoed in order to reduce the contamination from top-quark-related processes. Similarly, a $Z/\gamma^*(\rightarrow \mu^+\mu^-)$+jets control sample is selected by requiring the presence of two muons with $p_T > 10$ GeV and invariant mass in the range $66 < m_{\mu\mu} < 116$ GeV. In the $W(\rightarrow \mu\nu)$+jets and $Z/\gamma^*(\rightarrow \mu^+\mu^-)$+jets control regions, the $E_T^{miss}$ value is not corrected for the presence of the muons in the final state, motivated by the fact that these control regions are used to estimate the $Z(\rightarrow \nu\bar{\nu})$+jets, $W(\rightarrow \mu\nu)$+jets and $Z/\gamma^*(\rightarrow \mu^+\mu^-)$+jets backgrounds in the signal regions with no identified muons. The $E_T^{miss}$-based online trigger used in the analysis does not include muon information in the $E_T^{miss}$ calculation. This allows the collection of $W(\rightarrow \mu\nu)$+jets and $Z/\gamma^*(\rightarrow \mu^+\mu^-)$+jets control samples with the same trigger as for the signal regions.

A $W(\rightarrow e\nu)$+jets-dominated control sample was collected using online triggers that select events with an electron in the final state. The control sample is defined with an isolated electron candidate with $p_T > 30$ GeV, $30 < m_T < 100$ GeV, and no additional identified leptons in the final state. Electron candidates in the transition region between the barrel and endcaps of the electromagnetic calorimeter, $1.37 < |\eta| < 1.52$, are excluded. The $E_T^{miss}$ value is corrected by subtracting the contribution from the electron cluster in the calorimeter. In this way, the measured $E_T^{miss}$ in the event better reflects the magnitude of the $W$-boson $p_T$ in the final state, which is necessary for a proper implementation of the
$W$-boson $p_T$ reweighting procedure, as explained in section 3, that accounts for higher-order QCD and electroweak corrections. In order to suppress backgrounds from multijet processes with jets faking high-$p_T$ electrons, the events are required to have $E_T^{\text{miss}}/\sqrt{H_T} > 5 \text{ GeV}^{1/2}$, where in this case $E_T^{\text{miss}}$ still includes the contribution from the electron energy deposits in the calorimeter and $H_T$ denotes the scalar sum of the $p_T$ of the identified jets in the final state.

Finally, a control sample enriched in $t\bar{t}$ events is constructed using the same selection criteria as in the case of the $W(\rightarrow \mu\nu)+$jets but requiring that at least one of the jets is $b$-tagged.

6.2 Multijet background

The multijet background with large $E_T^{\text{miss}}$ mainly originates from the misreconstruction of the energy of a jet in the calorimeter and to a lesser extent is due to the presence of neutrinos in the final state from heavy-flavour hadron decays. In this analysis, the multijet background is determined from data, using the jet smearing method as described in ref. [83], which relies on the assumption that the $E_T^{\text{miss}}$ value of multijet events is dominated by fluctuations in the jet response in the detector, which can be measured in the data. For the IM1 and EM1 selections, the multijet background constitutes about 0.3% and 0.4% of the total background, respectively, and it is negligible for the other signal regions.

6.3 Non-collision background

Remaining non-collision background contributions in the signal regions, mostly from muons originating in the particle cascades due to beam-halo protons intercepting the LHC collimators, are estimated following closely the methods set out in ref. [82]. In particular, the jet timing, $t_j$, calculated from the energy-weighted average of the time of the jet energy deposits, defined with respect to the event time in nominal collisions, is used. A dedicated region enhanced in beam-induced background, defined by inverting the tight jet-quality selection imposed on the leading jet, is used to estimate the amount of non-collision background from the fraction of events with a leading-jet timing $|t_j| > 5 \text{ ns}$. The results indicate an almost negligible contribution from non-collision backgrounds in the signal regions.

6.4 Background fit

The use of control regions to constrain the normalization of the dominant background contributions reduces the relatively large theoretical and experimental systematic uncertainties, of the order of 20%–40%, associated with purely simulation-based background predictions in the signal regions. A complete study of systematic uncertainties is carried out, as detailed in section 7. To determine the final uncertainty in the total background, all systematic uncertainties are treated as Gaussian-distributed nuisance parameters in a fit based on the profile likelihood method [84], which takes into account correlations among systematic variations. The likelihood also takes into account cross-contamination between different background sources in the control regions.

The $E_T^{\text{miss}}$ distribution is the observable used. A simultaneous background-only likelihood fit to the $E_T^{\text{miss}}$ distributions in the $W(\rightarrow \mu\nu)+$jets, $W(\rightarrow e\nu)+$jets, $Z/\gamma^*(\rightarrow$
$\mu^+\mu^-$+jets, and top control regions is performed to normalize and constrain the background estimates in the signal regions. In the analysis, two different fitting strategies are considered, potentially giving slightly different results. A binned likelihood fit is performed using simultaneously all the exclusive $E_T^{\text{miss}}$ regions EM1–EM10, as described in section 5. The fit includes a single floating normalization factor common to all $W$+jets and $Z$+jets processes, and a single floating normalization factor for top-quark-related processes. The nuisance parameters, implementing the impact of systematic uncertainties, are defined bin-by-bin and correlations across $E_T^{\text{miss}}$ bins are taken into account. As a result, the fit exploits the information of the shape of the $E_T^{\text{miss}}$ distribution in constraining the normalization of $W/Z$+jets and top-quark-related background. In addition, one-bin likelihood fits are performed separately for each of the inclusive regions IM1–IM10. In this case, the two normalization factors for $W/Z$+jets and top-quark-related processes, respectively, and the nuisance parameters related to systematic uncertainties refer to the given $E_T^{\text{miss}}$ inclusive region.

The results of the background-only fit in the control regions are presented in table 2 for the $E_T^{\text{miss}} > 250$ GeV inclusive selection. The $W/Z$+jets background predictions receive a multiplicative normalization factor of 1.27. Similarly, top-quark-related processes receive a normalization factor of 1.06. When the binned likelihood fit is performed simultaneously over the different exclusive $E_T^{\text{miss}}$ regions, thus including information from the shape of the measured $E_T^{\text{miss}}$ distribution, the normalization factor of the $W/Z$+jets background predictions remains essentially unchanged, dominated by the low-$E_T^{\text{miss}}$ region, and that of the top-quark-related processes becomes 1.31, correlated with a less than 1σ pull of the top-quark-related uncertainties within the fit.

Figures 2 and 3 show the distributions of the $E_T^{\text{miss}}$ and the leading-jet $p_T$ in data and MC simulation in the different control regions. In this case, the MC predictions include the data-driven normalization factors as extracted from the binned likelihood fit to the different exclusive $E_T^{\text{miss}}$ bins. Altogether, the MC simulation provides a good description, within uncertainties, of the shape of the measured distributions in the different control regions.

### 7 Systematic uncertainties

In this section, the systematic uncertainties for both the background and signal models are presented. The impacts of the various sources of systematic uncertainty on the total background predictions are determined by the likelihood fits described in section 6.4. Inclusive and exclusive $E_T^{\text{miss}}$ selections are considered separately. For the latter, correlations of systematic uncertainties across $E_T^{\text{miss}}$ bins are taken into account. The impact of the different sources of uncertainty in representative inclusive $E_T^{\text{miss}}$ bins, as determined using one-bin likelihood fits, is presented below. Experimental and theoretical uncertainties in the signal model predictions are also presented.

#### 7.1 Background systematic uncertainties

Uncertainties in the absolute jet and $E_T^{\text{miss}}$ energy scales and resolutions [73] translate into uncertainties in the total background which vary between 0.5% for IM1 and 5.3% for IM10.
Figure 2. The measured (a), (c), (e) $E_T^{\text{miss}}$ and (b), (d), (f) leading-jet $p_T$ distributions in the $W(\to \mu\nu)+$jets, $W(\to e\nu)+$jets, and $Z/\gamma^*(\to \mu^+\mu^-)+$jets control regions, for the $E_T^{\text{miss}} > 250$ GeV inclusive selection, compared to the background predictions. The latter include the global normalization factors extracted from the fit. The error bands in the ratios include the statistical and systematic uncertainties in the background predictions as determined by the binned-likelihood fit to the data in the control regions. The last bin of the $E_T^{\text{miss}}$ and leading-jet $p_T$ distributions contains overflows. The contributions from multijet and non-collision backgrounds are negligible and are not shown in the figures.
Uncertainties related to jet quality requirements, pile-up description and corrections to the jet $p_T$ and $E_T^{\text{miss}}$ introduce a 0.9% to 1.8% uncertainty in the background predictions. Uncertainties in the $b$-tagging efficiency, relevant for the definition of the $W(\rightarrow \mu \nu)+\text{jets}$ and $t\bar{t}$ control regions, translate into an uncertainty in the total background that varies between 0.9% for IM1 and 0.5% for IM10. Uncertainties in soft contributions to $E_T^{\text{miss}}$ translate into an uncertainty in the total background yields that varies between 0.4% for IM1 and 1.7% for IM10.

Uncertainties in the simulated lepton identification and reconstruction efficiencies, energy/momentum scale and resolution [78, 85, 86] translate into an uncertainty in the total background which varies between 0.2% and 1.7% for IM1 and between 0.3% and 2.3% for IM10 selection.

Uncertainties in $W/Z+\text{jets}$ predictions [65, 87] related to the modelling of parton showers in SHERPA and the choice of PDFs translate into an uncertainty in the total background that varies between 0.8% for IM1 and 0.7% for IM10. Uncertainties on the implementation of higher-order QCD and electroweak parton-level calculations in the MC predictions,
Figure 3. The measured (a) $E_{T}^{\text{miss}}$ and (b) leading-jet $p_{T}$ distributions in the top control region, for the $E_{T}^{\text{miss}} > 250$ GeV inclusive selection, compared to the background predictions. The latter include the global normalization factors extracted from the fit. The error bands in the ratios include the statistical and systematic uncertainties in the background predictions as determined by the binned-likelihood fit to the data in the control regions. The last bin of the $E_{T}^{\text{miss}}$ and leading-jet $p_{T}$ distributions contains overflows. The contributions from multijet and non-collision backgrounds are negligible and are not shown in the figures.

as described in ref. [64], include: uncertainties in the QCD renormalization/factorization scales, affecting both the normalization and the shape of the predicted boson-$p_{T}$ distribution; uncertainties associated with the non-universality of QCD corrections across $W$+jets and $Z$+jets processes; uncertainties in electroweak corrections beyond NNLO, unknown electroweak NLO correction terms at very high boson-$p_{T}$, and limitations of the Sudakov approximation adopted in the calculation; uncertainties in the QCD and electroweak interference terms; and uncertainties on the implementation of the higher-order QCD corrections in SHERPA, affected by a limited MC statistics at large boson-$p_{T}$. Altogether, this translates into an uncertainty in the total background that varies between 0.4% for IM1 and 2% for IM10.

Theoretical uncertainties in the predicted background yields for top-quark-related processes include variations in parton-shower parameters and the amount of initial- and final-state soft gluon radiation, and the difference between predictions from different MC event generators [88]. This introduces an uncertainty in the total background of about 0.3% for IM1, becoming negligible at very high $E_{T}^{\text{miss}}$.

Uncertainties in the diboson contribution are estimated as the difference between the yields of the SHERPA and POWHEG event generators [89], after taking into account the difference between the cross sections, which is then summed in quadrature with a 6% theory uncertainty in the NLO cross section. This translates into an uncertainty on the total background of about 0.2% for IM1 and about 0.8% for IM10.

Uncertainties in the estimation of multijet and non-collision backgrounds translate into a 0.5% uncertainty of the total background for IM1 and have a negligible impact on the total background predictions at larger $E_{T}^{\text{miss}}$. Similarly, the 3.2% uncertainty in the integrated luminosity is included in the fit. It nearly cancels out in the data-driven determination
of the SM background and translates into an uncertainty in the total background yield of about 0.1% for IM1.

7.2 Signal systematic uncertainties

Sources of systematic uncertainty in the predicted signal yields are considered separately for each model of new physics using a common set of procedures. The procedures are described here, while the numerical uncertainties are given with the associated results for each model in section 8. Experimental uncertainties include those related to the jet and $E_{\text{T}}^{\text{miss}}$ reconstruction, energy scales and resolutions, and the integrated luminosity. Other uncertainties related to the jet quality requirements are negligible.

Uncertainties affecting the signal acceptance in the generation of signal samples include: uncertainties in the modelling of the initial- and final-state gluon radiation, determined using simulated samples with modified parton-shower parameters (by factors of two or one half); uncertainties due to PDFs and variations of the $\alpha_s(m_Z)$ value employed, as computed from the envelope of CT10, MMHT2014 [90] and NNPDF3.0 error sets; and uncertainties due to the choice of renormalization and factorization scales. In addition, theoretical uncertainties in the predicted cross sections, including PDF and renormalization- and factorization-scale uncertainties, are assessed separately for the different models.

8 Results and interpretation

The number of events in the data and the individual background predictions in several inclusive and exclusive signal regions, as determined using the background estimation procedure discussed in section 6.4, are presented in tables 3 and 4. The results for all the signal regions are summarized in table 5. Good agreement is observed between the data and the SM predictions in each case. The SM predictions for the inclusive selections are determined with a total uncertainty of 2.4%, 2.7%, and 9.7% for the IM1, IM5, and IM10 signal regions, respectively, which include correlations between uncertainties in the individual background contributions.

Figure 4 shows several measured distributions compared to the SM predictions in the region $E_{\text{T}}^{\text{miss}} > 250$ GeV, for which the normalization factors applied to the MC predictions, and the related uncertainties, are determined from the global fit carried out in exclusive $E_{\text{T}}^{\text{miss}}$ bins. For illustration purposes, the distributions include the impact of example ADD, SUSY, and WIMP scenarios. In general, the SM predictions provide a good description of the measured distributions. The differences observed in the jet multiplicity distribution do not have an impact in the results. Statistical tests using the binned profile likelihood fit described above, and considering different scenarios for new physics, give $p$-values for a background-only hypothesis in the range $0.01$–$0.04$, corresponding to agreement with the SM predictions within approximately $2.1\sigma$ to $1.7\sigma$.

The levels of agreement between the data and the SM predictions for the total number of events in inclusive and exclusive signal regions are translated into upper limits for the presence of new phenomena, using a simultaneous likelihood fit in both the control and signal regions, and the CL$_{s}$ modified frequentist approach [91]. The inclusive regions are
Table 3. Data and SM background predictions in the signal region for several inclusive $E_T^{miss}$ selections, as determined using separate one-bin likelihood fits in the control regions. For the SM prediction, both the statistical and systematic uncertainties are included. In each signal region, the individual uncertainties for the different background processes can be correlated, and do not necessarily add in quadrature to the total background uncertainty. The dash “-” denotes negligible background contributions.

used to set model-independent exclusion limits, and the exclusive regions are used for the interpretation of the results within different models of new physics. In general, the observed exclusion limits are worse than the expected sensitivity due to the slight excess of events in the data compared to the SM predictions, as shown in table 5.

8.1 Model-independent exclusion limits

A likelihood fit is performed separately for each of the inclusive regions IM1–IM10. As a result, model-independent observed and expected 95% confidence level (CL) upper limits on the visible cross section, defined as the product of production cross section, acceptance and efficiency, $\langle \sigma \rangle_{95}^{\text{obs}}$, are extracted from the ratio between the 95% CL upper limit on the number of signal events and the integrated luminosity, taking into consideration the systematic uncertainties in the SM backgrounds and the uncertainty in the integrated luminosity. The results are presented in table 6. Values of $\sigma \times A \times \epsilon$ above 531 fb (for IM1) and above 1.6 fb (for IM10) are excluded at 95% CL.

8.2 Weakly interacting massive particles

The results are translated into exclusion limits on WIMP-pair production. Different simplified models are considered with the exchange of an axial-vector, vector or a pseudoscalar mediator in the s-channel. In addition, a model with the exchange of a coloured scalar mediator is considered, as described in section 1.

In the case of the exchange of an axial-vector mediator, and for WIMP-pair production with $m_{Z_A} > 2m_\chi$, typical $A \times \epsilon$ values for the signal models with a 1 TeV mediator range from 25% to 0.4% for IM1 and IM10 selections, respectively. Very similar values are obtained in the case of the vector mediator, whereas $A \times \epsilon$ values in the range between 32% and 1% are computed for the pseudoscalar mediator model with $m_{Z_P} = 1$ TeV and $m_\chi = 10$ GeV. Finally, in the case of the coloured scalar mediator, $A \times \epsilon$ values in the range
from 35% to 0.7% are obtained for IM1 and IM10 selections, respectively, for a mediator mass of 1 TeV and \( m_\eta \gg m_\chi \).

The experimental uncertainties related to the jet and \( E_T^{\text{miss}} \) scales and resolutions introduce similar uncertainties in the signal yields for axial-vector, vector and pseudoscalar models. They vary between 2% and 7% for the IM1 selection and between 3% and 9% for the IM10 selection, depending on the parameters of the model. In the case of the coloured scalar mediator model, these uncertainties vary between 2% and 6% for IM1 and between 4% and about 10% for IM10. The uncertainty related to the modelling of the initial- and final-state radiation translates into a 20% uncertainty in the signal acceptance, common to all the s-channel models. In the case of the coloured scalar mediator model, this uncertainty varies between 10% and 30%, depending on the kinematic selection. The choice of different PDF sets results in up to a 20% uncertainty in the acceptance and up to a 10% uncertainty in the cross section, depending on the model considered. Varying the renormalization and factorization scales introduces up to 25% variations of the cross section and up to 10% change in the acceptance, depending on the model considered. In addition, the uncertainty in the integrated luminosity is included.

A simultaneous fit to the signal and control regions in the exclusive \( E_T^{\text{miss}} \) bins is performed, and used to set observed and expected 95% CL exclusion limits on the parameters of the model. Uncertainties in the signal acceptance times efficiency, the background predictions, and the luminosity are considered, and correlations between systematic uncertainties in signal and background predictions are taken into account. The fit accounts for the contamination of the control regions by signal events which a priori is estimated to be very small.

Figure 5(a) shows the observed and expected 95% CL exclusion contours in the \( m_{ZA} - m_\chi \) parameter plane for a simplified model with an axial-vector mediator, Dirac WIMPs, and couplings \( g_\eta = 1/4 \) and \( g_\chi = 1 \). In addition, observed limits are shown using \( \pm 1\sigma \) theoretical uncertainties in the signal cross sections. In the on-shell regime, the models with mediator masses up to 1.55 TeV are excluded for \( m_\chi = 1 \) GeV. For \( m_\chi < 1 \) GeV, the monojet analysis maintains its sensitivity for excluding DM models. This analysis loses sensitivity to the models in the off-shell regime, where cross sections are suppressed due to the virtual production of the mediator. Perturbative unitarity is violated in the parameter region defined by \( m_\chi > \sqrt{\pi/2} m_{ZA} \) [92]. The masses corresponding to the relic density [93] as determined by the Planck and WMAP satellites [9, 10], within the WIMP dark-matter model and in the absence of any interaction other than the one considered, are indicated in the figure as a line that crosses the excluded region at \( m_{ZA} \sim 1200 \) GeV and \( m_\chi \sim 440 \) GeV. The region towards lower WIMP masses or higher mediator masses corresponds to dark-matter overproduction.

The results are translated into 90% CL exclusion limits on the spin-dependent WIMP-proton scattering cross section \( \sigma_{SD} \) as a function of the WIMP mass, following the prescriptions from refs. [13, 93]. Among results from different direct-detection experiments, in figure 5(b) the exclusion limits obtained in this analysis are compared to the most stringent limits from the PICO direct-detection experiment [95]. The limit at the maximum value of the WIMP-proton scattering cross section displayed corresponds to the lowest excluded
Figure 5. (a) Axial-vector 95% CL exclusion contours in the $m_{Z_A}$-$m_\chi$ parameter plane. The solid (dashed) curve shows the observed (expected) limit, while the bands indicate the $\pm 1\sigma$ theory uncertainties in the observed limit and $\pm 1\sigma$ and $\pm 2\sigma$ ranges of the expected limit in the absence of a signal. The red curve corresponds to the set of points for which the expected relic density is consistent with the WMAP measurements (i.e. $\Omega h^2 = 0.12$), as computed with MadDM [94]. The region on the right of the curve corresponds to higher predicted relic abundance than these measurements. The region excluded due to perturbativity, defined by $m_\chi > \sqrt{2} m_{Z_A}$, is indicated by the hatched area. The dotted line indicates the kinematic limit for on-shell production $m_{Z_A} = 2 \times m_\chi$. The cyan line indicates previous results at 13 TeV [1] using 3.2 fb$^{-1}$. (b) A comparison of the inferred limits (black line) to the constraints from direct detection experiments (purple line) on the spin-dependent WIMP-proton scattering cross section in the context of the simplified model with axial-vector couplings. Unlike in the $m_{Z_A}$-$m_\chi$ parameter plane, the limits are shown at 90% CL. The results from this analysis, excluding the region to the left of the contour, are compared with limits from the PICO [95] experiment. The comparison is model-dependent and solely valid in the context of this model, assuming minimal mediator width and the coupling values $g_q = 1/4$ and $g_\chi = 1$.

values $m_{Z_A} = 45$ GeV and $m_\chi = 45$ GeV of the mediator and dark matter masses displayed in figure 5(a). This comparison is model-dependent and solely valid in the context of this particular model. In this case, stringent limits on the scattering cross section of the order of $2.9 \times 10^{-43}$ cm$^2$ ($3.5 \times 10^{-43}$ cm$^2$) for WIMP masses below 10 GeV (100 GeV) are inferred from this analysis, and complement the results from direct-detection experiments for $m_\chi < 10$ GeV. The kinematic loss of model sensitivity is expressed by the turn of the WIMP exclusion line, reaching back to low WIMP masses and intercepting the exclusion lines from the direct-detection experiments at around $m_\chi = 200$ GeV.

In figure 6, the results are translated into 95% CL exclusion contours in the $m_{Z_V}$-$m_\chi$ parameter plane for the simplified model with a vector mediator, Dirac WIMPs, and couplings $g_q = 1/4$ and $g_\chi = 1$. The results are obtained from those for the axial-vector model, taking into account the cross-section differences between models, motivated by the
Figure 6. Observed (solid line) and expected (dashed line) exclusions at 95% CL on the vector mediator models with $g_q = 1/4, g_\chi = 1.0$ and minimal mediator width, as a function of the assumed mediator and DM masses. The regions within the drawn contours are excluded. The red curve corresponds to the set of points for which the expected relic density is consistent with the WMAP measurements (i.e. $\Omega h^2 = 0.12$), as computed with MADDM [94]. The region on the right of the curve corresponds to higher predicted relic abundance than these measurements. The dotted line indicates the kinematic limit for on-shell production $m_{Z_V} = 2 m_\chi$.

The simplified model with a pseudoscalar mediator was considered with couplings to quarks and dark matter equal to unity. For WIMP masses in the range 0–300 GeV and $m_{Z_P}$ in the range 0–700 GeV, the analysis does not yet have enough sensitivity. As an example, figure 7 presents the analysis sensitivity in terms of 95% CL limits on the signal strength, $\mu \equiv \sigma_{95\% \, CL} / \sigma$, as a function of $m_{Z_P}$, for very light WIMPs, and as a function of $m_\chi$, for $m_{Z_P} = 10$ GeV. For mediator masses below 300 GeV and very light WIMPs, cross sections of the order of 2-to-3 times larger than that of the corresponding signal are excluded. For mediator masses above 300 GeV or larger dark-matter masses, the sensitivity of the analysis to this particular model vanishes rapidly.

Finally, figure 8 presents the observed and expected 95% CL exclusion contours in the $m_\eta$–$m_\chi$ parameter plane for the dark-matter production model with a coloured scalar mediator, Dirac WIMPs, and couplings set to $g = 1$. Mediator masses up to about 1.67 TeV are excluded at 95% CL for light dark-matter particles. In the case of $m_\chi = m_\eta$, masses up to 620 GeV are excluded.
Figure 7. Observed and expected 95% CL limits on the signal strength $\mu \equiv \sigma^{95\% \text{ CL}} / \sigma$ as a function of (a) the mediator mass for a very light WIMP and (b) the WIMP mass for $m_{Z_p} = 10$ GeV, in a model with spin-0 pseudoscalar mediator and $g_q = g_\chi = 1.0$. The bands indicate the $\pm 1\sigma$ theory uncertainties in the observed limit and the $\pm 1\sigma$ and $\pm 2\sigma$ ranges of the expected limit in the absence of a signal.

Figure 8. Exclusion contours at 95% CL in the $m_\chi - m_\eta$ parameter plane for the coloured scalar mediator model, with minimal width and coupling set to $g = 1$. The solid (dashed) curve shows the observed (expected) limit, while the bands indicate the $\pm 1\sigma$ theory uncertainties in the observed limit and $\pm 1\sigma$ and $\pm 2\sigma$ ranges of the expected limit in the absence of a signal. The red curve corresponds to the expected relic density, as computed with MadDM [94]. The kinematic limit for the mediator on-shell production $m_\eta = m_\chi$, is indicated by the dotted line.
8.3 Squark-pair production

Different models of squark-pair production are considered: stop-pair production with $\tilde{t}_1 \rightarrow c + \tilde{\chi}_1^0$, stop-pair production with $\tilde{t}_1 \rightarrow b + ff' + \tilde{\chi}_1^0$, sbottom-pair production with $\tilde{b}_1 \rightarrow b + \tilde{\chi}_1^0$, and squark-pair production with $\tilde{q} \rightarrow q + \tilde{\chi}_1^0$ ($q = u, d, c, s$). In each case separately, the results are translated into exclusion limits as a function of the squark mass for different neutralino masses.

The results are translated into exclusion limits on the pair production cross section of top squarks with $\tilde{t}_1 \rightarrow c + \tilde{\chi}_1^0$ (with branching fraction B=100%) as a function of the stop mass for different neutralino masses. The typical value of $A \times \epsilon$ of the selection criteria varies, with increasing stop and neutralino masses, between 0.7% and 1.4% for IM1, and between 0.04% and 1.3% for IM10. Observed and expected 95% CL exclusion limits are set as in the case of the WIMP models. In addition, observed limits are computed using ±1σ variations of the theoretical predictions for the SUSY cross sections. The uncertainties related to the jet and $E_T^{miss}$ scales and resolutions introduce uncertainties in the signal yields which vary between 1% and 3% for different selections and squark and neutralino masses. In addition, the uncertainty in the integrated luminosity is included. The uncertainties related to the modelling of initial- and final-state gluon radiation translate into a 7% to 17% uncertainty in the signal yields. The uncertainties due to the PDFs result in a 5% to 17% uncertainty in the signal yields. Finally, the variations of the renormalization and factorization scales introduce a 4% to 13% uncertainty in the signal yields.

Figure 9(a) presents the results in the case of the $\tilde{t}_1 \rightarrow c + \tilde{\chi}_1^0$ decays. The previous limits from the ATLAS Collaboration [1], corresponding to a luminosity of 3.2 fb$^{-1}$, are also shown. This analysis has significantly higher sensitivity at very low stop-neutralino mass difference. In the compressed scenario with the stop and neutralino nearly degenerate in mass, the exclusion extends up to stop masses of 430 GeV. The region with stop-neutralino mass differences below 5 GeV is not considered in the exclusion since in this regime the stop could become long-lived. Figure 9(b) shows the observed and expected 95% CL exclusion limits as a function of the stop and neutralino masses for the $\tilde{t}_1 \rightarrow b + ff' + \tilde{\chi}_1^0$ (B=100%) decay channel. For $m_{\tilde{t}_1} - m_{\tilde{\chi}_1^0} \sim m_b$, stop masses up to 390 GeV are excluded at 95% CL.

Figure 10(a) presents the observed and expected 95% CL exclusion limits as a function of the sbottom and neutralino masses for the $\tilde{b}_1 \rightarrow b + \tilde{\chi}_1^0$ (B=100%) decay channel. In the scenario with $m_{\tilde{b}_1} - m_{\tilde{\chi}_1^0} \sim m_b$, this analysis extends the 95% CL exclusion limits up to a sbottom mass of 430 GeV. In the case of light neutralinos with $m_{\tilde{\chi}_1^0} \sim 1$ GeV, sbottom masses up to 610 GeV are excluded at 95% CL. Finally, figure 10(b) presents the observed and expected 95% CL exclusion limits as a function of the squark mass and the squark-neutralino mass difference for $\tilde{q} \rightarrow q + \tilde{\chi}_1^0$ ($q = u, d, c, s$). In the compressed scenario with similar squark and neutralino masses, squark masses below 710 GeV are excluded at 95% CL. These results are a significant improvement on previous exclusion limits [1], and complement inclusive SUSY searches [96] in such mass-compressed regime.
Figure 9. Excluded regions at the 95% CL in the $\tilde{t}_1, \chi^0_1$ mass plane for (a) the decay channel $\tilde{t}_1 \to c + \chi^0_1$ ($B = 100\%$) and (b) the decay channel $\tilde{t}_1 \to b + f\bar{f} + \chi^0_1$ ($B=100\%$). The dotted lines around the observed limits indicate the range of observed limits corresponding to $\pm 1\sigma$ variations of the NLO SUSY cross-section predictions. The bands around the expected limits indicate the expected $\pm 1\sigma$ and $\pm 2\sigma$ ranges of limits in the absence of a signal. The results from this analysis are compared to previous results from the ATLAS Collaboration at $\sqrt{s} = 13$ TeV [1] using 3.2 fb$^{-1}$.

Figure 10. (a) Exclusion plane at 95% CL as a function of sbottom and neutralino masses for the decay channel $\tilde{b}_1 \to b + \chi^0_1$ ($B=100\%$). (b) Exclusion region at 95% CL as a function of squark mass and the squark-neutralino mass difference for $\tilde{q} \to q + \chi^0_1$ ($q = u, d, c, s$). The dotted lines around the observed limit indicate the range of observed limits corresponding to $\pm 1\sigma$ variations of the NLO SUSY cross-section predictions. The bands around the expected limit indicates the expected $\pm 1\sigma$ and $\pm 2\sigma$ ranges of limits in the absence of a signal. The results from this analysis are compared to previous results from the ATLAS Collaboration at $\sqrt{s} = 13$ TeV [1] using 3.2 fb$^{-1}$.
Table 7. The 95% CL observed and expected lower limits on the fundamental Planck scale in 
$4 + n$ dimensions, $M_D$, as a function of the number of extra dimensions $n$, considering nominal LO 
signal cross sections. The impact of the $\pm 1\sigma$ theoretical uncertainty on the observed limits and 
the expected $\pm 1\sigma$ range of limits in the absence of a signal are also given. Finally, the 95% CL 
observed limits after damping of the signal cross section for $\tilde{s} > M_D^2$ (see text) are quoted.

8.4 Large extra spatial dimensions

The level of agreement between the data and the SM predictions is also translated into limits 
on the parameters of the ADD model, as described in section 1. Only the signal regions 
with $E_T^{\text{miss}} > 400$ GeV, where the SM background is moderate and the shape difference 
between signal and the SM background becomes apparent, have sufficient sensitivity to 
ADD signal. The typical value of $A \times \epsilon$ of the selection criteria varies, as the number of 
extra dimensions $n$ increases from $n = 2$ to $n = 6$, between 13% and 17% for IM4 and 
between 0.8% and 1.4% for IM10.

The effect of experimental uncertainties related to jet and $E_T^{\text{miss}}$ scales and resolutions 
is found to be similar to the effect in the WIMP models. The uncertainties related to 
the modelling of the initial- and final-state gluon radiation translate into uncertainties in 
the ADD signal acceptance which vary between 11% and 13% with increasing $E_T^{\text{miss}}$ and 
approximately independent of $n$. The uncertainties due to the PDFs, affecting the predicted 
signal yields, increase from 11% at $n = 2$ to 43% at $n = 6$. Similarly, the variations of the 
renormalization and factorization scales introduce a 23% to 36% uncertainty in the signal 
yields, with increasing $n$.

Observed and expected 95% CL exclusion limits are set as in the case of the WIMP 
and SUSY models. The $-1\sigma$ variations of the ADD theoretical cross sections result in 
about a 7% to 10% decrease in the nominal observed limits, depending on $n$. Figure 11 
and table 7 present the results. Values of $M_D$ below 7.7 TeV at $n = 2$ and below 4.8 TeV 
at $n = 6$ are excluded at 95% CL, which improve on the exclusion limits from previous 
results using 3.2 fb$^{-1}$ of 13 TeV data [1].

As discussed in refs. [14, 97], the analysis partially probes the phase-space region with 
$\tilde{s} > M_D^2$, where $\sqrt{\tilde{s}}$ is the centre-of-mass energy of the hard interaction. This challenges 
the validity of the model implementation and the lower bounds on $M_D$, as they depend 
on the unknown ultraviolet behaviour of the effective theory. The observed 95% CL limits 
are recomputed after suppressing, with a weighting factor $M_D^2/\tilde{s}^2$, the signal events with 
$\tilde{s} > M_D^2$, here referred to as damping. This results in a negligible decrease of the quoted 
95% CL lower limits on $M_D$, as also shown in table 7.
Figure 11. Observed and expected 95% CL lower limits on the fundamental Planck scale in $4+n$ dimensions, $M_D$, as a function of the number of extra dimensions. The bands indicate the $\pm 1\sigma$ theory uncertainties in the observed limit and the $\pm 1\sigma$ and $\pm 2\sigma$ ranges of the expected limit in the absence of a signal. The 95% CL limits are computed with no suppression of the events with $\hat{s} > M_D^2$. The results from this analysis are compared to previous results from the ATLAS Collaboration using 3.2 fb$^{-1}$ of $\sqrt{s} = 13$ TeV data [1].

9 Conclusions

Results are reported from a search for new phenomena in events with an energetic jet and large missing transverse momentum in proton-proton collisions at $\sqrt{s} = 13$ TeV at the LHC, based on data corresponding to an integrated luminosity of 36.1 fb$^{-1}$ collected by the ATLAS detector in 2015 and 2016. The measurements are in agreement with the SM predictions. The results are translated into model-independent 95% CL upper limits on $\sigma \times A \times \epsilon$ in the range 531–1.6 fb, decreasing with increasing missing transverse momentum.

The results are translated into exclusion limits on WIMP-pair production. Different simplified models are considered with the exchange of an axial-vector, vector or a pseudoscalar mediator in the $s$-channel, and with Dirac fermions as dark-matter candidates. In the case of axial-vector or vector mediator models, mediator masses below 1.55 TeV are excluded at 95% CL for very light WIMPs (for coupling values $g_q = 1/4$ and $g_\chi = 1$), whereas the analysis does not have the sensitivity to exclude a pseudoscalar scenario. In the case of the axial-vector mediator model, the results are translated, in a model-dependent manner, into upper limits on spin-dependent contributions to the WIMP-nucleon elastic cross section as a function of the WIMP mass. WIMP-proton cross sections above $2.9 \times 10^{-43}$ cm$^2$ ($3.5 \times 10^{-43}$ cm$^2$) are excluded at 90% CL for WIMP masses below 10 GeV (100 GeV), complementing results from direct-detection experiments. In addition, a simplified model of dark-matter production including a coloured scalar mediator is considered, for which mediator masses below 1.67 TeV are excluded at 95% CL for very light WIMPs (with coupling set to $g = 1$).

Similarly, the results are interpreted in terms of a search for squark-pair production in a compressed-mass supersymmetric scenario. In the case of stop- and sbottom-pair...
production with $\tilde{t}_1 \rightarrow c + \tilde{\chi}_1^0$ or $\tilde{t}_1 \rightarrow b + f f' + \tilde{\chi}_1^0$ and $\tilde{b}_1 \rightarrow b + \tilde{\chi}_1^0$, respectively, squark masses below about 430 GeV are excluded at 95% CL. In the case of squark-pair production with $\tilde{q} \rightarrow q + \tilde{\chi}_1^0$ ($q = u, d, c, s$), squark masses below 710 GeV are excluded.

Finally, the results are presented in terms of lower limits on the fundamental Planck scale $M_D$ in $4 + n$ dimensions, versus the number of extra spatial dimensions in the ADD LED model. Values of $M_D$ below 7.7 TeV at $n = 2$ and below 4.8 TeV at $n = 6$ are excluded at 95% CL.

Acknowledgments

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.
