Measurement of $WW/WZ \to \ell\nu qq'$ production with the hadronically decaying boson reconstructed as one or two jets in $pp$ collisions at $\sqrt{s} = 8$ TeV with ATLAS, and constraints on anomalous gauge couplings

ATLAS Collaboration
CERN, 1211 Geneva 23, Switzerland

Abstract This paper presents a study of the production of $WW$ or $WZ$ boson pairs, with one $W$ boson decaying to $e\nu$ or $\mu\nu$ and one $W$ or $Z$ boson decaying hadronically. The analysis uses 20.2 fb$^{-1}$ of $\sqrt{s} = 8$ TeV $pp$ collision data, collected by the ATLAS detector at the Large Hadron Collider. Cross-sections for $WW/WZ$ production are measured in high-$p_T$ fiducial regions defined close to the experimental event selection. The cross-section is measured for the case where the hadronically decaying boson is reconstructed as two resolved jets, and the case where it is reconstructed as a single jet. The transverse momentum distribution of the hadronically decaying boson is used to search for new physics. Observations are consistent with the Standard Model predictions, and 95% confidence intervals are calculated for parameters describing anomalous triple gauge-boson couplings.

1 Introduction

Measurements of the production of two massive vector gauge bosons (hereafter, “diboson” production) represent an important test of the Standard Model (SM) of particle physics. Diboson measurements are powerful probes of the electroweak theory of the SM, in particular the structure of the triple gauge-boson couplings (TGCs) [1,2]. In addition, precise diboson measurements are a valuable test of higher-order calculations in quantum chromodynamics (QCD).

Measurements of $WW$ and $WZ$ production in the leptonic channels $\ell\nu \ell\nu$ and $\ell\nu\ell\ell$ ($\ell = e, \mu$) have been performed by the ATLAS and CMS collaborations in $pp$ collisions at $\sqrt{s} = 8$ TeV and $\sqrt{s} = 13$ TeV [3–9], and by the Tevatron experiments in $p\bar{p}$ collisions [10–13]. Measurements in the semileptonic channel $WV \to \ell\nu qq'$ ($V = W, Z$) have been performed by ATLAS [14] and CMS [15] at $\sqrt{s} = 7$ TeV, and by the Tevatron experiments in $p\bar{p}$ collisions [16,17]. The semileptonic channel offers features complementary to the leptonic channels. On the one hand, the presence of jets and the large background from $W +$ jets and $t\bar{t}$ production limit the experimental precision. On the other hand, the semileptonic channel has an approximately six times higher branching fraction than the fully leptonic channels. Also, for $WW$, the original diboson kinematics can be better reconstructed in an $\ell\nu qq'$ final state than in an $\ell\nu \ell\nu$ final state, since the latter has two invisible particles, rather than only one in $\ell\nu qq'$. Both of these advantages are particularly beneficial for searching for beyond-the-Standard-Model (BSM) enhancements of diboson production due to heavy new parti-
cles, which could modify the diboson spectrum at high transverse momentum ($p_T$) of the bosons [18].

It is possible to reconstruct the $V \to qq'$ decay as two small-radius jets ("small-R" jets, denoted by j) or as a single large-radius jet ("large-R" jet, denoted by J). Reconstructing the $V \to qq'$ decay as a large-R jet enables an increased reconstruction efficiency at high $p_T(V)$, thus improving the sensitivity to BSM signals. In addition, by applying grooming [19] techniques such as trimming [20] to the large-R jets, it is possible to better distinguish events containing $V \to qq'$ decays from background events [21].

In this paper, measurements of $WV \to \ell qq'$ fiducial cross-sections are presented in phase spaces containing a $V \to qq'$ candidate with high $p_T$. Two fiducial cross-sections are measured, in phase spaces chosen to closely match the two experimental selections used in this paper. The first event selection, denoted $WV \to \ell vjj$, reconstructs the $V \to qq'$ decay as two small-R jets, while the second one, denoted $WV \to \ell vJ$, reconstructs the $V \to qq'$ as a single large-R jet. Previous cross-section measurements of $WV \to \ell qq'$ have not exploited large-R jets.

A search for anomalous triple gauge-boson couplings (aTGCs) is also presented in this paper, using both the $WV \to \ell vqq'$ and $WV \to \ell vJ$ channels. Previous searches for charged aTGC contributions to $WV \to \ell qq'$ production have been conducted by the ATLAS Collaboration [14] using 7 TeV $pp$ collisions, by the CMS Collaboration [15,22] using 7 and 8 TeV $pp$ collisions, and by the D0 [23] and CDF [24] collaborations using $p\bar{p}$ collisions. Most published aTGC searches in the $WV \to \ell qq'$ channel have reconstructed the $V \to qq'$ as two small-R jets, with the exception of Ref. [22], which reconstructed the $V \to qq'$ as a single large-R jet.

2 Analysis overview

As mentioned above, measurements of $WV \to \ell qq'$ production are performed using either two small-R jets or a single large-R jet to reconstruct the hadronically decaying $V$ boson. For both channels, the leptonically decaying $W$ boson is reconstructed by requiring the presence of a lepton (electron or muon) and missing transverse momentum.

After applying stringent event selection requirements, the signal-to-background ratio remains quite low at 5–10%, because of the large $W + jets$ background. In order to distinguish the SM $WV$ signal from the background, the dijet mass distribution (in the $WV \to \ell vjj$ channel) or the mass distribution of the large-R jet (in the $WV \to \ell vJ$ channel) is used as a discriminating variable. The signal events peak near the $W/Z$ mass in these distributions, while the shape of the dominant $W + jets$ background is smoothly falling. In both channels, the signal is extracted from a fit to the dis-
calorimeter provides hadronic energy measurements in the range $|\eta|<1.7$, and liquid-argon-based endcap and forward calorimeters extend the EM and hadronic measurements up to $|\eta|=4.9$. A muon spectrometer, consisting of tracking and triggering detectors and three toroidal magnets, surrounds the calorimeters; it provides muon tracking and identification up to $|\eta|=2.7$ and triggering capability up to $|\eta|=2.4$.

A three-level trigger system is used to select the most interesting events for data storage [27]. An initial hardware-based trigger stage is followed by two software-based triggers, which reduce the final event rate to about 400 Hz.

4 Data and Monte Carlo samples

This analysis is based on an integrated luminosity of $20.2 \pm 0.4 \, \text{fb}^{-1}$ of 8 TeV $pp$ collisions recorded by the ATLAS detector in 2012. Events are required to pass one of several single-lepton triggers. The triggers require either an isolated electron or muon with $p_T > 24$ GeV, or an electron (muon) having $p_T > 60$ (36) GeV without an isolation requirement.

The nominal signal Monte Carlo (MC) samples consist of $qq' \rightarrow WV$ events generated at next-to-leading order (NLO) in QCD using MC@NLO v4.07 [28] interfaced with HERWIG v6.520 [29] and JIMMY v4.31 [30] for the simulation of parton showering, hadronization, and the underlying event. The CT10 parton distribution function (PDF) set [31] and parameter values from the AUET2 tune [32] are used for these samples. The $W$ and $Z$ bosons are generated on-shell by MC@NLO and decayed subsequently by HERWIG. The same MC configuration is also used to model sTGC contributions to $WV$ production, using an event reweighting feature built into MC@NLO.

In order to study systematic uncertainties, alternative $qq' \rightarrow WV$ samples are generated at NLO in QCD with POWHEG- BOX [33-35] using the CT10 PDF set. The parton showering and hadronization is modelled with PYTHIA 8.175 [36] using the AU2 tune [37]. Off-shell $W$ and $Z/\gamma^*$ decays are included; the $Z/\gamma^*$ decays have a requirement of $m_{qq'} > 20$ GeV and $m_{\ell\ell} > 20$ GeV.

Another set of alternative $qq' \rightarrow WV$ samples are generated with SHERPA v1.4.1 [38-41]. These samples are generated at leading order (LO) in QCD, but include up to three additional partons in the matrix element. Off-shell $W$ and $Z/\gamma^*$ decays are included; the $Z/\gamma^*$ decays have a requirement of $m_{qq'} > 4$ GeV and $m_{\ell\ell} > 4$ GeV.

Contributions from $gg \rightarrow H \rightarrow WW^*$ are only at the 1% level after applying the full event selection and are thus neglected. Signal MC samples for non-resonant $gg \rightarrow WW$ production are not used in the analysis, but the contribution from this process is estimated as described in Sect. 10, and included in the final cross-section predictions.

The $W +$ jets and $Z +$ jets backgrounds (collectively referred to as $V +$ jets) are modelled at LO in QCD with SHERPA v1.4.1, with up to four additional final-state partons. The CT10 PDF set is used for these samples, and they are normalized using inclusive cross-sections that are next-to-next-to-leading order (NNLO) in QCD, obtained using FEWZ [42]. For studies of systematic uncertainties, alternative $W +$ jets samples are generated with ALPGEN [43] interfaced with PYTHIA 6.426 [44], modelling the process at LO in QCD with up to five final-state partons. These additional samples use the Perugia 2011C tune [45] and the CTEQ6L1 PDF set [46].

The MC samples for the $t\bar{t}$ and single-top-quark ($t$-channel, $s$-channel, and $Wt$) processes (collectively referred to as top-quark processes) are generated with POWHEG-BOX [47-49] interfaced with PYTHIA 6.426 [44] (or PYTHIA 6.427 for the $t$-channel single-top-quark process). All of these samples use the CT10 PDF set for the matrix element, the CTEQ6L1 PDF set for the parton shower, and the Perugia 2011C tune.

The $ZZ$ background process is modelled with POWHEG interfaced with PYTHIA 8. The sample is normalized using the NLO prediction from MCFM [50,51].

The MC samples are passed through a GEANT4-based [52] simulation of the ATLAS detector [53]. For some of the MC samples, a fast simulation is used that makes use of a parameterization of the showers in the calorimeter. The hard-scattering processes in the MC samples are overlaid with simulated minimum-bias events in order to model additional collisions in the same or neighbouring bunch crossings (“pile-up”). The MC samples are reweighted so that their pile-up profile matches that observed in the data.

5 Event reconstruction

This analysis considers events with exactly one lepton (electron or muon), missing transverse momentum, and either two small-$R$ jets or one large-$R$ jet.

In each event, primary vertices are reconstructed, which must be formed from at least three tracks with $p_T > 400$ MeV. In case an event has multiple primary vertices (due to pile-up), the primary vertex with the highest $\sum p_T^2$ of the associated tracks is defined as the hard-scatter vertex.

Electron candidates are formed from energy clusters in the EM calorimeter matched to ID tracks. They are required to have $p_T > 30$ GeV and $|\eta| < 2.47$. Candidates in the transition region between the barrel and endcaps of the EM calorimeter, $1.37 < |\eta| < 1.52$, are excluded. In order to ensure that the electron candidates are consistent with having been produced at the hard-scatter vertex, the transverse impact parameter $d_0$ and longitudinal impact parameter $z_0$ are required to satisfy $|d_0|/\sigma_{d_0} < 5$ and $|z_0 \sin \theta| < 0.5$ mm,

$q \to p$ electron or muon with single-lepton triggers. The triggers require either an isolated detector in 2012. Events are required to pass one of several
respectively, where $\sigma_{d_0}$ is the uncertainty in the measured $d_0$. Both $d_0$ and $z_0$ are measured with respect to the hard-scatter vertex. Electron candidates must also satisfy the “tight” cut-based identification criteria from Ref. [54], based on track parameters and on the shower shapes in the calorimeter. Candidates must also pass isolation requirements based on calorimeter and track measurements. The calorimeter isolation requires $R_{\text{iso}}^{\text{cal}} < 0.14$, where $R_{\text{cal}}^{\text{iso}}$ is defined as the scalar transverse energy sum of the calorimeter energy deposits within a $\Delta R = \sqrt{(\Delta \eta)^2 + (\Delta \phi)^2} = 0.3$ cone centred on the electron candidate (excluding transverse energy from the candidate itself), divided by the $p_T$ of the electron candidate. Similarly, the track isolation requires $R_{\text{iso}}^{\text{ID}} < 0.07$, where $R_{\text{ID}}^{\text{iso}}$ is the scalar sum of the $p_T$ of the tracks within a $\Delta R = 0.3$ cone centred on the electron candidate (excluding the $p_T$ of the candidate’s track itself), divided by the electron candidate’s $p_T$.

Muon candidates are formed from the combination of a track in the muon spectrometer and one in the ID. They are required to have $p_T > 30$ GeV and $|\eta| < 2.4$. Their impact parameters must satisfy $|d_0|/\sigma_{d_0} < 3$ and $|z_0 \sin \theta| < 0.5$ mm. The candidates must also satisfy the isolation criteria $R_{\text{iso}}^{\text{cal}} < 0.07$ and $R_{\text{iso}}^{\text{ID}} < 0.07$, where $R_{\text{cal}}^{\text{iso}}$ and $R_{\text{ID}}^{\text{iso}}$ are defined analogously to the electron case.

Small-$R$ jets are reconstructed from topological energy clusters [55] in the calorimeter using the anti-$k_t$ algorithm [56] with radius parameter $R = 0.4$. The jet energies are calibrated as described in Ref. [57] and are corrected for pile-up. They are required to have $p_T > 25$ GeV and $|\eta| < 2.5$ for the $WV \rightarrow \ell vij$ channel. Small-$R$ jets with $|\eta| < 4.5$ are used in the $WV \rightarrow \ell vJ$ channel as part of a jet veto (see Sect. 6). In order to remove jets originating from pile-up, small-$R$ jets having $p_T < 50$ GeV and $|\eta| < 2.4$ are required to have an absolute value of the “jet vertex fraction” variable (JVF) [58] greater than 0.5.

In the $WV \rightarrow \ell vJ$ channel, large-$R$ jets are reconstructed using the anti-$k_t$ algorithm with radius parameter $R = 1.0$, and are trimmed [20] using a subjet radius of 0.2 and a momentum-fraction parameter $f_{\text{cut}} = 0.05$; the trimming procedure discards soft subjets from the large-$R$ jets and reduces their sensitivity to pile-up [21]. They are required to have $p_T > 200$ GeV and $|\eta| < 2.0$. The energies of the small-$R$ and large-$R$ jets and the masses of the large-$R$ jets are calibrated using $p_T$- and $\eta$-dependent scale factors [57,59].

If an electron and a muon candidate share the same ID track, the electron candidate is rejected. If a small-$R$ jet is within $\Delta R = 0.2$ of a selected electron candidate, the jet is rejected; if the jet is within $0.2 < \Delta R < 0.4$ of a selected electron, the electron candidate is rejected. Muon candidates are rejected if they are within $\Delta R = 0.4$ of a small-$R$ jet. Finally, large-$R$ jets are rejected if they are within $\Delta R = 1.0$ of a selected lepton candidate. In the object selection stage, small-$R$ jets and large-$R$ jets are allowed to overlap; however, in the event selection stage a $\Delta R$ requirement is applied between the small-$R$ and large-$R$ jets, as explained in Sect. 6.

The missing transverse momentum $E_T^{\text{miss}}$ is computed as the negative vector sum of the transverse momentum of all the detected objects in the event, including reconstructed jets, photons, electrons, and muons. An additional “soft term” is included that accounts for the $p_T$ of clusters in the calorimeter which are not associated with any specific reconstructed object [60]. The magnitude of $E_T^{\text{miss}}$ is denoted $E_T^{\text{miss}}$.

6 Event selection

Two independent sets of event selection criteria are developed that target different event topologies: the $WV \rightarrow \ell vij$ selection, described in Sect. 6.1, and the $WV \rightarrow \ell vJ$ selection, described in Sect. 6.2. The $WV \rightarrow \ell vij$ channel and $WV \rightarrow \ell vij$ channel differ significantly from one another in their kinematics, expected signal yields, and signal-to-background ratios. Therefore, the event selection criteria are optimized separately for the two channels.

For both the $WV \rightarrow \ell vij$ and $WV \rightarrow \ell vJ$ selections, all events are required to contain at least one primary vertex. Events must have exactly one good electron or muon candidate. Events are vetoed if they contain any additional lepton candidates that have $p_T > 15$ GeV and satisfy a looser set of selection criteria.

6.1 $WV \rightarrow \ell vij$ channel

Events must have $E_T^{\text{miss}} > 40$ GeV and a transverse mass\(^2\) $m_T > 40$ GeV. Events must contain exactly two small-$R$ jets. The requirement of exactly two jets substantially reduces the background from top-quark decays. The pseudorapidity separation of the selected jets is required to satisfy $\Delta \eta(j_1, j_2) < 1.5$, in order to improve the signal-to-background ratio.

In order to reduce the multijet background not removed by the $E_T^{\text{miss}} > 40$ GeV requirement, an azimuthal-angle difference between the $E_T^{\text{miss}}$ direction and the direction of the leading-$p_T$ jet of $|\Delta \phi(j_1, E_T^{\text{miss}})| > 0.8$ is required. Also, both the $V \rightarrow q\bar{q}'$ and $W \rightarrow \ell v$ candidates must pass requirements on their transverse momenta: $p_T(j_j) > 100$ GeV and $p_T(W \rightarrow \ell v) > 100$ GeV, where $p_T(W \rightarrow \ell v) \equiv |E_T^{\text{miss}} + \vec{p}_T(\ell)|$. These $p_T$ requirements enhance the separation between the signal and background distributions in the dijet mass.

As described in Sect. 8, the signal is extracted using a maximum-likelihood (ML) fit to the dijet mass ($m_{jj}$) distribution.

\(^2\) The transverse mass is defined as $m_T \equiv \sqrt{(E_T^{\text{miss}} + p_T(\ell))^2 - |\vec{E}_T^{\text{miss}} + \vec{p}_T(\ell)|^2}$, where $p_T(\ell)$ is the transverse momentum of the lepton candidate.
tion. In the dijet mass calculation, the mass of each individual jet is set to zero, which makes the variable easier to model in the MC simulation. Since the signal is extracted from a fit to \( m_{jj} \), only a loose requirement is made on this variable: 40 GeV < \( m_{jj} < 200 \) GeV.

6.2 \( WV \to \ell v \bar{J} \) channel

Events must contain exactly one large-\( R \) jet with \( p_T > 200 \) GeV and \(|\eta| < 2.0\). The backgrounds from top-quark decays are suppressed by rejecting events containing any small-\( R \) jets with \( p_T > 25 \) GeV and \(|\eta| < 4.5\) that are separated from the large-\( R \) jet by \( \Delta R(j, J) > 1.0 \). In order to suppress the multijet background, a requirement of \( E_T^{\text{miss}} > 50 \) GeV is applied. The trimmed mass of the large-\( R \) jet, \( m_1 \), must be 50 GeV < \( m_1 < 170 \) GeV, and the signal is measured from the ML fit to \( m_1 \).

Since the \( WV \to \ell v \bar{J} \) and \( WV \to \ell v J \) event selections are done independently, some events pass both selections. About 10% of the signal MC events that pass the \( WV \to \ell v \bar{J} \) selection also pass the \( WV \to \ell v J \) selection, while about 50% of the signal MC events that pass the \( WV \to \ell v J \) selection also pass the \( WV \to \ell v \bar{J} \) selection.

7 Background estimation

The methods for estimating the expected background yields and kinematic distributions are described in this section. The estimates from this section are used as inputs to the ML fit in which the signal is measured while the backgrounds are allowed to vary within their systematic uncertainties. In that ML fit, the \( V + \) jets normalization is allowed to vary without constraint, so the estimates given in this section are pre-fit estimates.

Most of the backgrounds (\( W + \) jets, \( Z + \) jets, \( t \bar{t}, \) single top-quark, and \( ZZ \)) are estimated using MC simulation, with data-driven corrections applied in some cases, as described later in this section. By far the largest background in the analysis is from \( W + \) jets, followed by top-quark production. Despite the latter background’s subdominant contribution, it plays an important role because it contains contributions from real \( W \to q q' \) decays, which make it more difficult to distinguish from the signal. About 80% of the top-quark background is due to \( t \bar{t} \) production, and the remainder comes from single-top-quark production.

Multijet processes form another source of background. Multijet events can pass the event selection if they contain non-prompt leptons (produced from semileptonic decays of \( c- \) and \( b- \) hadrons) or “fake” leptons (resulting from misidentified jets). The multijet backgrounds are estimated using data-driven techniques, as described in Sects. 7.1 and 7.2.

7.1 \( WV \to \ell v jj \) channel

The \( V + \) jets background prediction is MC-based, but data-driven corrections are applied to the MC prediction in order to improve the description of the jet kinematics. A \( V + \) jets control region (CR) is defined identically to the signal region, except that the region \( 65 \) GeV < \( m_{jj} < 95 \) GeV is vetoed, in order to remove most of the signal events. One-dimensional reweighting functions of the variables \( p_T(j_1) \) and \( \Delta \phi(jj) \) are derived from this \( V + \) jets CR. These reweighting functions have approximately 10% effects on the shapes of the \( p_T(j_1) \) and \( \Delta \phi(jj) \) distributions. Data–MC comparisons in the \( V + \) jets CR are shown in Fig. 1, before and after application of the reweighting functions. All further results in this paper are shown with these two reweighting functions applied to the \( V + \) jets MC samples. The same reweighting functions are used for both the \( W + \) jets and \( Z + \) jets processes. It was checked that the reweighting functions obtained from the low-\( m_{jj} \) and high-\( m_{jj} \) portions of the \( V + \) jets control region are compatible.

The top-quark background is modelled with MC simulation, and is cross-checked in a validation region containing three small-\( R \) jets, one of which is \( b\)-tagged using the MV1 algorithm [61,62]. Good agreement is observed between the data and the MC simulation, so no corrections are applied to the prediction. The background from \( ZZ \) events is also modelled with MC simulation.

The data-driven multijet background estimate makes use of a multijet CR. The multijet CR is formed by selecting events in data that pass the same selection requirements as for the signal region, except that the lepton quality criteria are modified in order to produce a CR enriched in non-prompt and fake leptons. Lepton candidates satisfying these modified criteria are called “anti-identified” lepton candidates. Anti-identified muon candidates must have a non-negligible impact parameter, \(|d_0|/\sigma_{d_0} > 4\), and satisfy looser isolation criteria than the signal muon candidates. Anti-identified electrons must fail the “tight” but satisfy the “medium” cut-based identification criteria from Ref. [54], and are also required to contain a hit in the innermost layer of the pixel detector. In addition, the isolation criteria are modified for anti-identified electron candidates, in order to enrich the sample in non-prompt and fake electrons.

The shapes of the kinematic distributions [such as \( m_{jj}, E_T^{\text{miss}}, \) and \( p_T(jj) \)] of the multijet background are estimated from events in the multijet CR, after subtracting the MC predictions of the non-multijet contributions to the CR. These non-multijet contributions are about 20% (50%) of the total in the electron (muon) channel. The overall multijet background event yield is estimated from a fit to the \( E_T^{\text{miss}} \) distribution of events that pass the full signal region selection, except that the requirements on \( E_T^{\text{miss}} \) and \( \Delta \phi(j_1), E_T^{\text{miss}} \) (and also \( \Delta \eta(j,j) \) and \( m_T \) for the muon channel) are removed in order
to enhance the number of multijet events. This selection is referred to as the extended signal region. In this $E_T^{\text{miss}}$ fit, the multijet $E_T^{\text{miss}}$ shape is estimated from an extended multijet CR, defined analogously to the extended signal region, but requiring the lepton to pass the anti-identified-lepton selection. The $E_T^{\text{miss}}$ shapes of the other backgrounds are estimated using MC samples. The multijet event yield obtained from this fit is then extrapolated to the signal region, using the ratio of events in the multijet CR and the extended multijet CR, corrected for non-multijet contributions. The multijet background estimates are performed separately for the electron and muon channels. Only about 5% of the total multijet background is in the muon channel.

The expected signal and background yields in the $WV \rightarrow \ell\nu jj$ signal region are given in Table 1, and compared to the number of events observed in data. The predictions for the $m_{jj}$ distribution shapes of the signal and backgrounds are shown in Fig. 2a.

7.2 $WV \rightarrow \ell\nu J$ channel

In the $WV \rightarrow \ell\nu J$ channel, the $W + \text{jets}$, $Z + \text{jets}$, and top-quark backgrounds are estimated using MC samples. The MC predictions for the two largest backgrounds ($W + \text{jets}$ and top-quark production) are corrected by scale factors obtained from dedicated control regions.

The top-quark control region (top CR) is formed by events satisfying the signal region selection, except that the presence of at least one small-$R$ $b$-tagged jet with $p_T > 25$ GeV and $\Delta R(j, J) > 1.0$ is required instead of applying the nominal veto on small-$R$ jets. The jets are $b$-tagged using the MV1 algorithm [61,62], using a working point with a $b$-tagging efficiency of about 70% and a gluon/light-quark jet rejection.

Fig. 1 Comparisons between the data and the prediction in the $V + \text{jets}$ control region of the $WV \rightarrow \ell\nu jj$ channel. The top panel shows the data and prediction before applying the $p_T(j_1)$ and $\Delta \phi(j_1, j_2)$ kinematic reweighting to the $V + \text{jets}$ predictions. The distributions shown are a $p_T$ of the leading jet and b $\Delta \phi$ between the leading jet and sub-leading jet. Overflow is included in the last bin of the $p_T(j_1)$ plot. The bottom panel shows the ratio of the SM prediction to the data before and after applying the kinematic reweighting to the $V + \text{jets}$ prediction. The hatched bands indicate the statistical uncertainty in the predictions.
Fig. 2 The shapes of a the predicted $m_{jj}$ distributions in the $WV \rightarrow \ell\nu jj$ signal region and b the predicted $m_J$ distributions in the $WV \rightarrow \ell\nu J$ signal region, for the signal (peaked near 80 GeV) and various background processes. The distributions are normalized to unity.

Fig. 3 Comparison between data and prediction in the $WV \rightarrow \ell\nu J$ channel for a $m_J$ in the top CR, and b $p_T(J)$ in the $W+\text{jets}$ CR. A scale factor is applied to the top-quark background prediction in the top CR and the $W+\text{jets}$ CR, and a scale factor is applied to the $W+\text{jets}$ background prediction (which is part of the “$V+\text{jets}$” histogram) in the $W+\text{jets}$ CR. The hatched bands indicate the systematic uncertainty of the prediction. For the $V+\text{jets}$ component, only shape systematic uncertainties are included in the bands.

Factor of over 100 in $t\bar{t}$ events. About 90% of the events in this top CR originate from top-quark backgrounds. There is a deficit in data in the top CR relative to the MC prediction, which is attributed to a mismodelling of the top-quark backgrounds. A global scale factor of 0.87 for the top-quark backgrounds is obtained from this CR, after subtracting the prediction for non-top-quark backgrounds. The data in the top CR is shown in Fig. 3a, compared to the SM prediction after application of the top-quark scale factor. This scale factor is applied to the top-quark background predictions in the signal region.

The control region for the $W+\text{jets}$ background ($W+\text{jets}$ CR) is obtained by applying the standard signal region selection, but adding the requirement that $m_J < 65$ GeV or $m_{J} > 95$ GeV. This additional $m_J$ requirement removes almost all of the $WV$ signal events and also a large fraction of the top-quark events. About 85% of the events in this CR originate from $W+\text{jets}$ backgrounds. The top-quark background prediction in the $W+\text{jets}$ CR is scaled by the top-quark scale factor obtained above. A data deficit is observed in the $W+\text{jets}$ CR relative to the prediction. A global scale factor of 0.84 is obtained for the $W+\text{jets}$ background, after subtracting the expected contributions from the other signal/background processes. A comparison between the data and the prediction in the $W+\text{jets}$ CR is shown in Fig. 3b, after application of the $W+\text{jets}$ scale factor. The $W+\text{jets}$ scale factor is applied to the $W+\text{jets}$ prediction in the signal region.
The method for estimating the multijet background is similar to that used in the $WV \rightarrow \ell v_{jj}$ channel. As in the $WV \rightarrow \ell v_{jj}$ channel, a multijet CR is defined by requiring an “anti-identified” lepton candidate. The shapes of the kinematic distributions are estimated from this CR using the same method as in the $WV \rightarrow \ell v_{jj}$ channel. The non-multijet background contributions to the CR are about 6% of the total. The multijet event yield is estimated from a fit to the $E_T^{\text{miss}}$ distribution, as in the $WV \rightarrow \ell v_{jj}$ channel, but the only requirement that is removed for the definition of the extended signal region/multijet CR is the $E_T^{\text{miss}} > 50$ GeV requirement. The multijet background is found to be negligible for the muon channel, so only the contribution in the electron channel is considered for the final results.

The numbers of expected and observed events in the $WV \rightarrow \ell v_{jj}$ signal region are summarized in Table 1. The previously mentioned top-quark and $W$+jets scale factors are applied to the predictions. The contribution from $ZZ$ events is expected to be very small in the $WV \rightarrow \ell v_{jj}$ channel, so it is neglected. The nominal predictions for the $m_{jj}$ distribution shapes of the signal and backgrounds are shown in Fig. 2b.

8 Cross-section extraction

The fiducial cross-section $\sigma_{\text{fid}}$ for $WV \rightarrow \ell q\bar{q'}$ production is measured independently for the $WV \rightarrow \ell v_{jj}$ and $WV \rightarrow \ell v_{JJ}$ phase spaces, in both cases using the formula:

$$\sigma_{\text{fid}} = \frac{N_{WV}}{L \cdot D_{\text{fid}}},$$

where $N_{WV}$ is the measured signal yield, $L$ is the integrated luminosity, and $D_{\text{fid}}$ is a factor that corrects for experimental acceptance and efficiencies. Since this analysis measures $N_{WV}$ as the sum of the $WW$ and $WZ$ processes, which can each have different acceptances and efficiencies, $D_{\text{fid}}$ is given by:

$$D_{\text{fid}} = f_{\text{fid}}^{WW} \cdot C^{WW} + \left(1 - f_{\text{fid}}^{WW}\right) \cdot C^{WZ},$$

where the $C^{WW}$ are reconstruction correction factors and the variable $f_{\text{fid}}^{WW}$ is the predicted ratio of the $WW$ fiducial cross-section to the $WW + WZ$ fiducial cross-section. The $C^{WW}$ and $f_{\text{fid}}^{WW}$ values are estimated from MC simulation. The $C^{WW}$ factors are defined as the predicted number of $WV$ signal events passing the reconstruction-level event selection divided by the number of $WV$ events in the fiducial phase space defined with generator-level particles. The $C^{WW}$ factors account for reconstruction inefficiencies, resolution effects, and for contributions to the signal region from $WV$ events that do not decay to $\ell vq\bar{q'}$ (such as $WV \rightarrow \tau q\bar{q'}$ or $WV \rightarrow \ell v\ell\nu$); the latter are included in the $C^{WW}$ numerator and not in the denominator. The cross-section $\sigma_{\text{fid}}$ is measured for the sum of the electron and muon channels, so $D_{\text{fid}}$ is computed as a weighted average over the electron and muon channels. The fiducial cross-section measurement therefore assumes that the signal MC simulation correctly predicts the ratio of $WW$ to $WZ$ and of electrons to muons. The value of $D_{\text{fid}}$ is $0.83 \pm 0.05$ in the $WV \rightarrow \ell v_{jj}$ channel and $0.60 \pm 0.08$ in the $WV \rightarrow \ell v_{JJ}$ channel, including systematic uncertainties (see Sect. 9).

The fiducial phase spaces for the $WV \rightarrow \ell v_{jj}$ and $WV \rightarrow \ell v_{JJ}$ channels are defined in Sects. 8.1 and 8.2, respectively. These fiducial phase spaces partially overlap. In order to cope with the small signal-to-background ratios in this analysis (5–10%), the cross-section $\sigma_{\text{fid}}$ is extracted using a binned ML fit to the $m_{jj}$ distribution (in the $WV \rightarrow \ell v_{jj}$ analysis) or the $m_{jj}$ distribution (in the $WV \rightarrow \ell v_{JJ}$ analysis). The ML fits are performed on the sum of the electron and muon channels. It was cross-checked that the electron and muon channels are compatible, in both the $WV \rightarrow \ell v_{jj}$ and $WV \rightarrow \ell v_{JJ}$ channels.

In the ML fits, the value of $\sigma_{\text{fid}}$ and the $V$+jets background yield are both free to vary without constraint. Systematic uncertainties in the signal and backgrounds are incorporated in the fit by including nuisance parameters that are allowed to vary within prior constraints. The nuisance parameters allow the luminosity, $D_{\text{fid}}$, the non-$V + jets$ background yields, and the $m_{jj}$ and $m_{jj}$ shapes of the signal and background distributions to vary within their systematic uncertainties. The correlations between the uncertainty in $D_{\text{fid}}$ and the uncertainty in the signal $m_{jj}/m_{jj}$ shapes are accounted for in the fit. The sources of systematic uncertainty and the methods to assess these uncertainties are described in detail in Sect. 9.

8.1 $WV \rightarrow \ell v_{jj}$ fiducial phase space

The $WV \rightarrow \ell v_{jj}$ fiducial phase space is defined to closely match the experimental event selection. The phase-space definition requires a $WV$ pair with the bosons decaying as $V \rightarrow qq'$ and $W \rightarrow \ell v$, where $\ell = e, \mu$. Events containing other kinds of $WV$ decay channels (such as $WV \rightarrow \ell v\ell v$ events or $WV \rightarrow \tau qq'$ with the $\tau$ decaying to $\ell + X$), are not included in the fiducial phase-space definition. Such $WV$ events can still pass the experimental event selection (where they are included in the signal category), and they are accounted for in the $D_{\text{fid}}$ definition.

Leptons selected in the fiducial region must have $p_T(\ell) > 30$ GeV and $|\eta(\ell)| < 2.47$. The four-momentum of the lepton is modified by adding to it the four-momenta of all the photons within $\Delta R = 0.1$, excluding photons produced by hadron decays. Particle-level anti-$k_T$, $R = 0.4$ jets are constructed using as constituents all stable particles, excluding muons and neutrinos. Stable particles are defined as those having a mean lifetime of $\tau > 30$ ps. The particle-level jets must have $p_T > 25$ GeV and $|\eta| < 2.5$. Jets within $\Delta R = 0.2$...
Table 2 Summary of the fiducial phase-space definitions. All the specified selection criteria are applied at the particle level as specified in the text. The notations “j” and “J” refer to identified selection criteria are applied at the particle level as specified in Table 2.

of a selected electron are rejected, and then leptons within $\Delta R = 0.4$ of a remaining jet are rejected. The true $E_T^{\text{miss}}$ in the event is defined as the magnitude of the vector $p_T$ sum of all the neutrinos.

The event must have exactly one lepton and two $R = 0.4$ jets matching the above definitions. The remaining requirements for the fiducial phase space are summarized in Table 2, and are analogous to the experimental event selection, but are defined using the lepton, $E_T^{\text{miss}}$, and particle-level jets described in this section.

8.2 $WV \rightarrow \ell \nu J$ fiducial phase space

As in the $WV \rightarrow \ell \nu jj$ channel, the fiducial phase-space definition requires a $WV$ pair with $V \rightarrow q\bar{q}'$ and $W \rightarrow \ell \nu$. Leptons, $E_T^{\text{miss}}$, and particle-level $R = 0.4$ jets are defined in the same way as in the $WV \rightarrow \ell \nu jj$ channel, except that two sets of leptons and small-$R$ jets are considered: central leptons (small-$R$ jets) are required to have $|\eta| < 2.47$ ($|\eta| < 2.5$), and extended leptons and small-$R$ jets are required to have $|\eta| < 4.5$. Particle-level large-$R$ jets are defined by applying the anti-$k_t$ algorithm with radius parameter $R = 1.0$ to all stable particles, excluding muons and neutrinos. No trimming is applied to these jets. The large-$R$ jets are required to have $p_T > 200$ GeV and $|\eta| < 2.0$. Central (extended) small-$R$ jets that are within $\Delta R = 0.2$ of a central (extended) electron are rejected. Then, central leptons are rejected if they are within $\Delta R = 0.4$ of a remaining central small-$R$ jet. Large-$R$ jets are rejected if they are within $\Delta R = 1.0$ of any remaining central leptons. Events are required to contain exactly one central lepton and one large-$R$ jet with the above definitions, and events are discarded if they contain any extended small-$R$ jets with $\Delta R(j, j) > 1.0$. The event must also have $E_T^{\text{miss}} > 50$ GeV, and the large-$R$ jet must have a mass greater than 50 GeV. The fiducial phase-space definition is summarized in Table 2.

9 Systematic uncertainties

Systematic uncertainties in the measured $\sigma_{\text{ fid}}$ can be due to uncertainties in $\mathcal{L}$, $D_{\text{ fid}}$, and/or $N_{WV}$. Uncertainties in the measured $N_{WV}$ can in turn be due to uncertainties in the background yields or in the shapes of the kinematic distributions ($m_{jj}, m_1$) of the signal and backgrounds (hereafter called “shape uncertainties”). The dominant systematic uncertainties in the $\sigma_{\text{ fid}}$ measurement are those affecting the measured $N_{WV}$.

A wide variety of detector-related experimental uncertainties are considered, which affect $D_{\text{ fid}}$, the predicted background yields, and the signal and background shapes. The most important of these uncertainties are those related to the jet reconstruction. Uncertainties in the small-$R$ jet energy scale and resolution are accounted for [57,63]. In the $WV \rightarrow \ell \nu J$ channel, uncertainties in the large-$R$ jet energy and jet mass scales are also taken into account. The scale uncertainties of the large-$R$ jets are estimated using a double-ratio method that compares calorimeter- and track-jets in data and MC simulation [21]. The energy and mass resolution uncertainties of large-$R$ jets are estimated by smearing the jet energies/masses so as to degrade the resolutions by 20%; this approach is based on prior studies of large-$R$ jets [64,65]. The systematic uncertainty due to the JVF requirement is also included [66]. In addition to the jet-related uncertainties, there are also systematic uncertainties in the electron and muon reconstruction (including triggering, object reconstruction, identification, and the energy scale and resolution) [54,67–70]. The effects of the jet and lepton uncertainties are propagated to the $E_T^{\text{miss}}$ calculation, and an additional systematic uncertainty in the soft terms entering the $E_T^{\text{miss}}$ calculation is also included [60].

In the cross-section fits, the $V +$ jets yield is taken to be a free parameter, while several uncertainties in the modelling of its shape are accounted for (in addition to the shape uncertainties from the previously mentioned detector effects). Systematic uncertainties in the $V +$ jets shape are estimated by varying the MC event generator used (SHHERPA compared to ALPGEN+PYTHIA). The differences between the predictions of the two generators are taken as additional systematic uncertainties. Additional uncertainties in the $V +$ jets shape are estimated by varying the renormalization and factorization scales by factors of 2 and 0.5, and by varying the scale used.
in SHERPA for matching the matrix elements to the parton showers [39] from its nominal value of 20 GeV to alternative values of 15 GeV and 30 GeV. In the $WV \rightarrow \ell vjj$ channel, the uncertainty in the shapes of the $V + \text{jets}$ predictions due to the two kinematic reweighting functions (see Sect. 7.1) is estimated by including the full difference between applying and not applying each reweighting function as additional systematic uncertainties. In the $WV \rightarrow \ell vjj$ channel, an uncertainty of 10% in the $(W + \text{jets})/(Z + \text{jets})$ cross-section ratio is also included; this uncertainty is ignored in the $WV \rightarrow \ell vJ$ channel as it has a negligible effect.

For the $t\bar{t}$ background, uncertainties due to the matrix-element event generator, parton shower/hadronization model, and amount of initial- and final-state radiation are all included. The theoretical uncertainties in the top-quark background cross-sections are also taken into account. In the $WV \rightarrow \ell vJJ$ channel, instead of using the theoretical cross-section uncertainty, the top-quark background is assigned a normalization uncertainty of 14% to account for the uncertainty in the data-driven scale factor. Systematic uncertainties in the multijet background estimate are also included, which affect both its normalization and its shape. These uncertainties are derived from studies of variations of the data-driven estimate, such as changing the control region definitions and varying the non-multijet background subtraction. The uncertainty in the multijet yield amounts to 30% (100%) for the electron (muon) channel in the $WV \rightarrow \ell vjj$ channel. In the $WV \rightarrow \ell vJ$ channel, an uncertainty of 50% is assigned to the multijet yield in the electron channel, while the multijet background is neglected in the muon channel. A 30% uncertainty is assigned to the $ZZ$ event yield in the $WV \rightarrow \ell vjj$ channel, to account for uncertainties in the $ZZ$ cross-section and the extrapolation to the fiducial phase space.

Additionally, the uncertainty in the modelling of pile-up interactions is accounted for [71]. The uncertainty in the integrated luminosity is also included, computed as described in Ref. [72]. The statistical uncertainty of the MC samples is taken into account, which affects each bin in the ML fits in an uncorrelated way.

Uncertainties in the signal shapes and in the $D_{\text{fid}}$ parameter due to variations of the signal model are computed by varying the renormalization and factorization scales by factors of 2 and 0.5, and by comparing the nominal MC@NLO signal samples to alternative samples generated with SHERPA and POWHEG +PYTHIA 8. The effect on $D_{\text{fid}}$ from the uncertainties in the CT10 PDF set is also taken into account; the PDF uncertainty has a negligible impact on the signal shapes.

The measured $\sigma_{\text{fid}}$ values are compared to theoretical predictions from MC@NLO. The uncertainty in the theoretical $\sigma_{\text{fid}}$ prediction is calculated including the uncertainties due to renormalization and factorization scales. Since the fiducial phase spaces contain a veto on additional jets, the Stewart–Tackmann procedure [73] is used to estimate the scale uncertainties. These uncertainties are also propagated to the theoretical $f_{\text{fid}}^{WW}$ value which enters into the $D_{\text{fid}}$ calculation, although the effect of this on the measured $\sigma_{\text{fid}}$ is very small (~0.1%). PDF-induced uncertainties in the theoretical prediction are also taken into account.

10 Cross-section results

The result of the ML fit to the $m_{\text{jj}}$ distribution for the $WV \rightarrow \ell vjj$ channel is shown in Fig. 4. The fit is performed on the sum of events in the electron and muon channels. The observed significance is $4.5\sigma$, including statistical and systematic uncertainties, while the expected significance, calculated using the Asimov data set [74], is $5.2\sigma$. The fitted $V + \text{jets}$ background normalization is $1.02 \pm 0.01$ times its pre-fit value, while the fitted top-quark background normalization is $0.96 \pm 0.10$ times its pre-fit value.

The fiducial cross-section for the signal process is extracted from the fit as described in Sect. 8, and the result is $\sigma_{\text{fid}}(WV \rightarrow \ell vjj, \text{observed}) = 209 \pm 28(\text{stat}) \pm 45(\text{syst}) \text{ fb}$. The impacts of the various systematic uncertainties on the cross-section measurement are shown in Table 3. The measurement can be compared to the theoretical prediction of $\sigma_{\text{fid}}(WV \rightarrow \ell vjj, \text{theory}) = 225 \pm 13 \text{ fb}$.

3 The significance is calculated based on the profile-likelihood ratio of the background-only and signal-and-background hypotheses. This ratio is converted to a significance using the asymptotic approximation [74].
The theoretical prediction is obtained using MC@NLO for the $qq' \rightarrow WV$ prediction. The $gg \rightarrow WV$ prediction is also included, and is calculated using the total NLO $gg \rightarrow WV$ cross-section prediction [75] multiplied by the $qq' \rightarrow WV$ acceptance from MC@NLO. The $gg \rightarrow WV$ contribution increases the fiducial cross-section prediction by 4% in both the $WV \rightarrow \ell\nu jj$ and $WV \rightarrow \ell\nu J$ channels. Given the relatively small $gg \rightarrow WV$ contribution, the possible differences in acceptance between the $gg \rightarrow WV$ and $qq' \rightarrow WV$ processes are neglected. The uncertainty in the MC@NLO prediction is described in Sect. 9.

The result of the $m_{J}$ fit for the $WV \rightarrow \ell\nu J$ channel is shown in Fig. 5. Although the signal-to-background ratio is better in this case than in the $WV \rightarrow \ell\nu jj$ channel, the total number of signal events is much smaller. The observed significance of the result is $1.3\sigma$ (including statistical and systematic uncertainties), compared to an expected significance of $2.5\sigma$. The fitted $V + \text{jets}$ (top-quark) background normalization is $1.01 \pm 0.04 (1.06 \pm 0.20)$ times its pre-fit value.

The extracted fiducial cross-section for the signal process is

$$\sigma_{\text{fid}}(WV \rightarrow \ell\nu J, \text{observed}) = 30 \pm 11(\text{stat}) \pm 22(\text{syst}) \text{ fb}$$

which is compatible with the theoretical prediction of

$$\sigma_{\text{fid}}(WV \rightarrow \ell\nu J, \text{theory}) = 58 \pm 15 \text{ fb}$$

The breakdown of the uncertainties contributing to the fiducial cross-section measurement is shown in Table 4.

The cross-section measurements are summarized in Fig. 6. As mentioned in Sect. 8, the two cross-section measurements

$WV \rightarrow \ell\nu jj$

**Fig. 5** The observed $m_{J}$ distribution in the $WV \rightarrow \ell\nu J$ signal region, overlaid with the post-fit background and signal estimates. The hatched band indicates the total uncertainty of the fit result.

**Fig. 6** The ratios of the measured fiducial cross-sections to the cross-sections predicted by MC@NLO, for the $WV \rightarrow \ell\nu jj$ and $WV \rightarrow \ell\nu J$ phase spaces. The $WV \rightarrow \ell\nu jj$ and $WV \rightarrow \ell\nu J$ phase spaces partially overlap.
are performed in partially overlapping phase spaces. The uncertainty in the theory prediction is significantly larger in the $WV \rightarrow \ell\nu J$ channel than in the $WV \rightarrow \ell\nu jj$ channel. The theoretical uncertainty in the $WV \rightarrow \ell\nu J$ channel is dominated by the scale uncertainties, which are particularly large because of the aggressive jet veto in this channel (only about 30% of signal MC events pass the jet veto in the $WV \rightarrow \ell\nu J$ channel, compared to about 80% in the $WV \rightarrow \ell\nu jj$ channel).

11 Constraints on anomalous gauge couplings

In many extensions of the SM, diboson production can be modified, such as through new resonances that couple to bosons. If the scale of new physics is sufficiently high, new resonances may not be visible in the current data; however, diboson production could still be affected below the new-physics scale, in the form of modified couplings. One common framework for parameterizing new physics in diboson production is an effective field theory [77,78] of the form:

$$L_{WWX}^{WV} \propto \left[ (1 + \Delta g^X_1)(W_{\mu\nu}W_{\mu\nu} - W^{+\mu}W^{-\mu})X^\nu + (1 + \Delta \kappa_X)W^{+\mu}W^{-\nu}X^{\mu\nu} + \frac{\lambda_X}{m_W^2}W^{+\nu}W^{-\rho}X^{\mu\rho} \right],$$

where $X = Z$ or $\gamma$, $W^{\pm}_{\mu\nu} = \partial_\mu W^{\pm}_{\nu} - \partial_\nu W^{\pm}_{\mu}$, and $X^{\mu\nu} = \partial_\mu X_\nu - \partial_\nu X_\mu$. The six parameters $\lambda_X$, $\Delta \kappa_X$, and $\Delta g^X_1$ (hereafter called “aTGC parameters”) are all zero in the SM. The parameter $\Delta g^Z_1$ is zero because of EM gauge invariance, leaving five free aTGC parameters, which describe deviations of the triple gauge-boson couplings from their SM predictions. It is common to apply the so-called LEP constraint [76], which imposes $SU(2) \times U(1)$ gauge invariance, and which reduces the number of independent aTGC parameters to three, by introducing the following constraints: $\lambda_Z = \lambda_{\gamma}$ and $\Delta g^Z_1 = \Delta \kappa_Z + \Delta \kappa_{\gamma} \tan^2 \theta_W$, where $\theta_W$ is the weak mixing angle. Since aTGC parameters lead to violation of unitarity at high energies, form factors are often applied to them in order to ensure unitarity:

$$\alpha \rightarrow \frac{\alpha}{\left(1 + \frac{\hat{s}}{\Lambda_{EF}}\right)^2},$$

where $\alpha$ is one of the aTGC parameters, $\hat{s}$ is the square of the diboson invariant mass, and $\Lambda_{EF}$ is the form factor’s energy scale.

An alternative framework for describing modifications of diboson production is an effective field theory (EFT) [77,78] that is assumed to be valid below an energy scale $\Lambda$, and which introduces three CP-conserving dimension-six operators:

$$O_W = (D_\mu \Phi)^T W^{\mu\nu} (D_\nu \Phi),$$
$$O_B = (D_\mu \Phi)^T B^{\mu\nu} (D_\nu \Phi),$$
$$O_{WWW} = Tr[W_{\mu\nu} W^{\rho\sigma} W^{\rho\sigma}].$$

Here, $\Phi$ is the Higgs doublet field, $D_\mu$ is the covariant derivative, and $W^{\mu\nu}$ and $B^{\mu\nu}$ are the field strength tensors of the $W$ and $B$ gauge boson fields. The coefficients of these operators (EFT parameters), $c_W/\Lambda^2$, $c_B/\Lambda^2$, and $c_{WWW}/\Lambda^2$, are zero in the SM and can be related to the LEP-constraint aTGC parameters as follows:

$$c_W/\Lambda^2 = \frac{2}{m_Z^2} \Delta g^Z_1,$$
$$c_B/\Lambda^2 = \frac{2}{m_W^2} \Delta \kappa_Z - \frac{2}{m_Z^2} \Delta g^Z_1,$$
$$c_{WWW}/\Lambda^2 = \frac{2}{\lambda^2} \frac{g^2}{m_W^2} \lambda.$$

This relation only holds if no form factor is applied to the aTGCs. The effect of aTGC/EFT parameters on the $H \rightarrow WW$ process is neglected.

The aTGC and EFT parameters both tend to increase the diboson cross-section at high $p_T(V)$ and high invariant mass of the diboson system. Both the $WV \rightarrow \ell\nu jj$ channel and the $WV \rightarrow \ell\nu J$ channel can be used to search for these BSM enhancements. The $WV \rightarrow \ell\nu J$ channel, although currently less sensitive as a SM $WV$ measurement, is expected to provide a higher sensitivity to the aTGC/EFT models, because of the better efficiency at high $p_T(V)$. On the other hand, the $WV \rightarrow \ell\nu jj$ channel, where the SM $WV$ measurement is clearly established, is useful as a complementary search channel that probes a different energy range.

In this analysis, the new-physics search uses signal regions with exactly the same event selection as the cross-section measurements, except that the $m_{jj}$ requirement is tightened to 65 GeV $< m_{jj} <$ 95 GeV in the $WV \rightarrow \ell\nu jj$ channel and the $m_{jj}$ requirement is tightened to 65 GeV $< m_{jj} <$ 95 GeV in the $WV \rightarrow \ell\nu J$ channel. These tighter requirements lead to an increase in the signal-to-background ratio. In the $WV \rightarrow \ell\nu jj$ channel, events which fail the $m_{jj}$ requirement (i.e. 40 GeV $< m_{jj} <$ 65 GeV or 95 GeV $< m_{jj} <$ 200 GeV) are put into a sideband control region. The ZZ background is neglected in the new-physics search, due to its very small expected contribution.

The search makes use of the $p_T(jj)$ ($WV \rightarrow \ell\nu jj$ channel) or $p_T(J)$ ($WV \rightarrow \ell\nu J$ channel) distribution. Hereafter, $p_T(V_{rec})$ is used to refer to both $p_T(jj)$ and $p_T(J)$. The $p_T(V_{rec})$ distributions of the events in the signal regions are shown in Fig. 7. This figure also shows the expected enhancement at high $p_T(V_{rec})$ in the presence of different EFT parameter values. As can be seen from the figure, no significant deviation from the SM prediction is observed; there-
Fig. 7 The observed $p_T(jj)$ distribution in the $WV \to \ell jj$ aTGC signal region, and b $p_T(J)$ distribution in the $WV \to \ell xJ$ aTGC signal region, overlaid with the background and signal prediction. The expected BSM enhancements due to anomalous values of the EFT parameter $c_{WW}/\Lambda^2$ are shown, for $c_{WW}/\Lambda^2 = 4$ TeV$^{-2}$ and $c_{WW}/\Lambda^2 = 8$ TeV$^{-2}$. The hatched bands indicate the systematic uncertainty in the SM prediction. The histograms are displayed with the binning that is used for the computation of the confidence intervals for the aTGC and EFT parameters. The last bin includes overflow.

Table 5 The observed and expected 95% confidence intervals for the aTGC parameters without the LEP constraint. The confidence intervals are computed separately for the $WV \to \ell jj$ and $WV \to \ell xJ$ channels, and are calculated both for $\Lambda_{PF} = 5$ TeV and $\Lambda_{PF} = \infty$ (i.e. no form factor). The confidence intervals for each parameter are calculated while fixing the other parameters to zero.

Therefore, 95% confidence intervals are computed for the aTGC and EFT parameters. The confidence intervals are computed from binned ML fits to the $p_T(V_{rec})$ distributions. The intervals are calculated using a frequentist Feldman–Cousins approach [79]. In the $WV \to \ell jj$ channel, simultaneous fits to the $p_T(V_{rec})$ distributions in the signal region and sideband CR are used, while in the $WV \to \ell xJ$ channel, only the $p_T(V_{rec})$ distribution in the signal region is used. Since the $WV \to \ell jj$ and $WV \to \ell jj$ selections overlap, the confidence intervals are calculated separately for the $WV \to \ell jj$ and $WV \to \ell jj$ selections. In the fits, the SM $WV$ and background predictions are allowed to vary within their uncertainties. The measured cross sections of Sect. 10 are consistent with theoretical SM $WV$ predictions, but have large associated uncertainties; for this reason the theoretical prediction is used here. The systematic uncertainties in the normalizations and $p_T(V_{rec})$ shapes of the signal and backgrounds are accounted for through nuisance parameters. The systematic uncertainties that have the largest impact on the results are the jet-related uncertainties (in both channels) and the uncertainty from the limited size of the MC samples (in the $WV \to \ell jj$ channel).

The observed 95% confidence intervals for the aTGC parameters are shown in Table 5, without applying the LEP...
constraint. The confidence intervals for a given aTGC parameter are computed while fixing the other aTGC parameters to zero. The confidence intervals are shown separately for the $WV \rightarrow \ell vjj$ and $WV \rightarrow \ell vJ$ channels, and the expected confidence intervals under the SM hypothesis are also shown for comparison. Confidence intervals for the aTGC parameters are shown for $\Lambda_{FF} = 5$ TeV and for the case of no form factor (equivalent to $\Lambda_{FF} = \infty$). The value of $\Lambda_{FF} = 5$ TeV is chosen in order to ensure unitarity over the range of aTGC parameter values to which this analysis is sensitive [80].

The $WV \rightarrow \ell vJ$ selection has significantly better sensitivity to the aTGC parameters. No combination of the $WV \rightarrow \ell vjj$ and $WV \rightarrow \ell vJ$ constraints is performed, since it is expected that the $WV \rightarrow \ell vJ$ channel would dominate the combination. The sensitivity to the aTGC parameters in the $WV \rightarrow \ell vJ$ channel mainly comes from the $p_T(V_{rec}) > 600$ GeV bins, whereas the sensitivity in the $WV \rightarrow \ell vjj$ channel mainly comes from the 300–600 GeV bins. Since the $WV \rightarrow \ell vjj$ channel probes a lower $p_T(V_{rec})$ range, its sensitivity is less degraded by the form factors (which have a larger effect at higher $p_T$) than the $WV \rightarrow \ell vJ$ channel.

In addition, the observed and expected confidence intervals for the aTGC parameters in the LEP-constraint scenario are given in Table 6 for $\Lambda_{FF} = \infty$.

The observed and expected confidence intervals for the EFT parameters are shown in Table 7, separately for the $WV \rightarrow \ell vjj$ and $WV \rightarrow \ell vJ$ selections. Confidence regions for combinations of two EFT parameters are shown in Fig. 8; for each combination the third EFT parameter is held fixed to zero. Although the constraints from the $WV \rightarrow \ell vjj$ channel are less stringent than those from the $WV \rightarrow \ell vJ$ channel, they probe a complementary phase space. The sensitivity of the $WV \rightarrow \ell vJ$ channel is similar to the most sensitive previous analyses to publish constraints on these parameters [3,5,6,22]. The $WV \rightarrow \ell vJ$ channel probes a similar phase space to Ref. [22]; these analyses benefit from their ability to reconstruct high-$p_T V \rightarrow q\bar{q}'$ decays.

### 12 Conclusion

The production of $WV \rightarrow \ell vqq'$, with $V$ being a $W$ or $Z$ boson, is measured using 20.2 fb$^{-1}$ of $pp$ collisions at 8 TeV at the LHC with the ATLAS detector. The measurements focus on $WV$ production where the bosons have large transverse momentum. Fiducial cross-sections for the $WV \rightarrow \ell vqq'$ process are measured in two different, but partially overlapping, phase spaces.

The first phase space, denoted $WV \rightarrow \ell vjj$, targets a hadronically decaying $V$ boson whose decay products can be distinguished as two $R = 0.4$ jets. In this phase space, the $WV \rightarrow \ell vqq'$ process is measured with a significance of 4.5σ, and the fiducial cross-section is measured to be $209 \pm 8\text{,(stat)} \pm 4\text{(syst)}$ fb, in agreement with the MC@NLO prediction of 225 ± 13 fb.

The second phase space, denoted $WV \rightarrow \ell vJ$, contains a single $R = 1.0$ jet consistent with the collimated decay products of a high-$p_T V$ boson. The $WV$ process is measured with a significance of 1.3σ in this phase space. The fiducial cross-section for this phase space is measured to be $30 \pm 11\text{,(stat)} \pm 22\text{(syst)}$ fb, consistent with the MC@NLO prediction of 38 ± 15 fb.

The events are also used to search for new physics modifying triple gauge-boson vertices, which could lead to enhance-
The 95% confidence-level regions for combinations of two EFT parameters. (a) $c_{WWW}/\Lambda^2$ and $c_{WW}/\Lambda^2$, (b) $c_{WWW}/\Lambda^2$ and $c_{W}/\Lambda^2$, (c) $c_{BB}/\Lambda^2$ and $c_{W}/\Lambda^2$. The expected and observed confidence regions are shown for the $WV \rightarrow \ell\nu jj$ channel (outer contours) and the $WV \rightarrow \ell\nu J$ channel (inner contours). When computing the confidence regions for two parameters, the third EFT parameter is held fixed to zero.
