University of Amsterdam

Abstract

This paper introduces the task of few-shot common action localization in time and space. Given a few trimmed support videos containing the same but unknown action, we strive for spatio-temporal localization of that action in a long untrimmed query video. We do not require any class labels, interval bounds, or bounding boxes. To address this challenging task, we introduce a novel few-shot transformer architecture with a dedicated encoder-decoder structure optimized for joint commonality learning and localization prediction, without the need for proposals. Experiments on reorganizations of the AVA and UCF101-24 datasets show the effectiveness of our approach for few-shot common action localization, even when the support videos are noisy. Although we are not specifically designed for common localization in time only, we also compare favorably against the few-shot and one-shot state-of-the-art in this setting. Lastly, we demonstrate that the few-shot transformer is easily extended to common action localization per pixel.

1. Introduction

The goal of this paper is to localize an action in video time and space, without the need for class labels, interval bounds or box annotations. Class-agnostic action proposals, for either temporal, e.g. [13, 25, 32] or spatio-temporal, e.g., [18, 48, 50] action localization, have the same goal. However, to be effective they need to generate many proposals and a secondary supervised step to find the best fitting one. To avoid the need for extensive supervision, Feng et al. [7] introduced one-shot localization of actions in time and space. They rely on proposals as well, but rather than using class supervision, a matching model between a trimmed support video and a long untrimmed video determines the best proposal. In similar spirit, Yang et al. [45] introduced common action localization in time. Given a few trimmed support videos containing the same (unknown) action, they are able to localize with the aid of proposals an action in a long untrimmed video. Their setup also avoids the need for temporal and class annotations. In this work, we extend upon both [7] and [45] and propose the new task of few-shot common action localization in time and space. Our approach does not require any box annotations or class labels to obtain the spatio-temporal localization, and neither do we need proposals as in [7, 45]. All we require are a handful of trimmed videos showing a common unnamed action, see Figure 1.

Our approach to few-shot common action localization is inspired by the success of transformers [1] in object detection as demonstrated by Carion et al. [3]. Their approach eliminates the need for proposals and the accompanying hand-crafted components, while maintaining competitive performance. Such a proposal-free method avoids the needle-in-the-haystack problem with proposals in object detection, a problem which is even more severe in spatio-temporal action localization. Further, they exploit the versatile and powerful relation modeling capability of transformers. This is naturally suitable for common action localization as well, where the core challenge is to model the commonality between the few support videos and the single query video. To that end, we propose a transformer with an encoder-decoder structure that is adapted for our task of few-shot common action localization in time and space.

Figure 1: Few-shot common action localization in time and space. Given a few trimmed support videos sharing a common action, our proposed few-shot transformer is able to localize the spatio-temporal tubelet of the common action in a long untrimmed query video, without requiring the action class label, or any temporal or spatial annotations.
We make three contributions. First, we introduce the task of few-shot common action localization in time and space. We localize the spatio-temporal tube encapsulating an unknown action, based on the commonality between a long untrimmed query video and a few trimmed support videos containing the same unknown action. Second, we propose a few-shot transformer with a dedicated encoder-decoder structure optimized for joint commonality learning and localization prediction, without the need for proposals. As a third contribution, we reorganize the videos in AVA [11] and UCF101-24 [36] to allow for evaluation of few-shot common action localization in time and space. Our experiments show the effectiveness of our approach, even when support videos are noisy. Moreover, we demonstrate compatibility to few-shot and one-shot temporal action localization, outperforming the respective state-of-the-art. Last but not least, we show that the few-shot transformer easily extends to common action localization per pixel. Code: https://github.com/PengWan-Yang/few-shot-transformer.

2. Related work

**Few- and zero-shot action localization.** Yang et al. [44] introduce few-shot action-class localization in time, where a few (or at least one) positive labeled and several negative labeled videos steer the localization via an end-to-end meta-learning strategy. The strategy relies on sliding windows to swipe over the untrimmed query video to generate fixed boundary proposals. Xu et al. [43] also temporally localize an action from a few positive labeled and several negative labeled videos. They adopt a region proposal network [31] to produce proposals with flexible boundaries. Zhang et al. [49] perform few-shot temporal action localization, where video-level annotations are needed. They construct a multi-scale feature pyramid to directly produce temporal features at variable scales. For spatio-temporal action localization, a number of works have investigated a zero-shot perspective by linking actions to relevant objects [19,21,28,29], or by leveraging trimmed videos used for action classification [17]. Soonro et al. [35] tackle action localization in an unsupervised setting, where no annotations are provided at all. While zero-shot and unsupervised action localization show promise, current approaches are not competitive with few-shot alternatives, hence we focus on the few-shot setting. Rather than relying on a few positive and many negative action class labels, like [43,44], our action localization approach does not require any predefined positive or negative action class labels, neither does it need any temporal or spatial bounds. All we require is that the few trimmed support videos have the same action in common. Moreover, we attempt to localize the common action both in time and in space.

**Localization by commonality.** Compared with few-shot localization, common localization further frees the need for labels. It localizes according to the commonality between the query and support inputs. Kang et al. [22] and Hu et al. [14] detect the common object in an image by a few examples containing the same object, without the need to know their class name. They both adopt a one-stage detector architecture with a feature reweighting module. Also for common object detection, Fan et al. [6] rely on the support-guided region proposal network in a two-stage approach to produce support-related proposals and match each proposal with support images. Video relocalization by Feng et al. [8] introduces temporal action localization in an untrimmed query video from a single unlabeled support video, along with a one-stage approach. Yang et al. [45] propose few-shot temporal localization of the common action. While their two-stage architecture is more general and effective than [8], it depends on proposals and several hand-crafted components, such as anchors in the proposal generation and non-maximum suppression in a post-processing step [45]. Compared to these works, we aim for common localization in time and space simultaneously.

Closest to our work is spatio-temporal video relocalization by Feng et al. [7], which extends their temporal video relocalization [8] to time and space from a single support video. Feng et al. [7] propose a warp LSTM to align spatio-temporal information between adjacent frames to embed long-term dependencies. They produce a large set of proposals for each query video clip to match each proposal with their single support video. Like Yang et al. [45], their method requires hand-designed components in the proposal generation and post-processing step. Compared to spatio-temporal video relocalization, we consider a more general and realistic setting, where more than one support video can be used. We propose a transformer network architecture, which avoids the need for proposals. Lastly, we also generalize to common temporal and pixel-level action localization.

**Transformers in vision.** Transformers were introduced by Vaswani et al. [40] as a powerful attention-based building block for machine translation. Jaderberg et al. [16] proposed to spatially transform image feature maps, conditional on the feature map itself, alike the self-attention mechanism, even before the standard transformer structure became popular. Gavrilyuk et al. [9] propose an actor-transformer to learn and selectively extract information relevant for group activity recognition. Ye et al. [47] are the first to employ a self-attention mechanism via a transformer to contextualize instances in the few-shot image classification setting. Recently, Carion et al. [3] propose a transformer encoder-decoder structure for object detection to eliminate the need for many hand-designed components, while still demonstrating good performance. Encouraged by this early success of transformers for various vision challenges, we propose a transformer for few-shot common action localization based on the hypothesis that the transformer’s attention mechanism
can efficiently process sequences of spatio-temporal information and model the relation between query and support videos. Our one-stage transformer frees the need for proposals and other pre-defined components, typical in common action localization, while obtaining better localization results in time and space.

3. Method

Our goal is to localize the spatio-temporal tubelet of an action in an untrimmed query video based on the common action in the trimmed support videos. Note we have no access to the action class label or its time and space boundary annotations. Following recent work on supervised spatio-temporal action detection e.g., [11, 20, 46], our approach performs common localization at clip level, i.e., common localization results are first obtained from each query video clip and then linked to build the action tubes across the whole query video. Our approach consists of three main stages. First, we split the video into multiple clips. Then the query clips are separate representations, to obtain spatio-temporal representations. Each query clip feature is aligned with previous clip features using our common attention block. Then our few-shot transformer further processes the features, fuses the support features into the query clip feature, and transforms the input embeddings by aggregating it with the fused feature. Finally, a 3-layer feed-forward neural network and a linear projection are added on top of the output embeddings from the few-shot transformer to make the final tubelet prediction.

Our method is summarized in Figure 2 and described for each stage in more detail next.

3.1. Video feature extractor

We adopt an I3D network [4] as our backbone to obtain spatio-temporal representations of a single query video and a few support videos. The weights of the backbone network are shared between the support and query videos. For the support videos, we feed the whole video into the backbone directly, one by one. Let \( f^s \in \mathbb{R}^{S \times TWH \times C} \) denote the representation of all \( S \) support videos with their spatio-temporal dimensions flattened, and \( f^i \in \mathbb{R}^{TWH \times C} \) denote the feature of the \( i \)-th support video. For a single untrimmed query video, we first split the video into multiple clips. Then the query clips go through the backbone network. Let \( f^q \in \mathbb{R}^{N \times T'WH \times C} \) denote the representation of all \( N \) query video clips, and \( f_j^q \in \mathbb{R}^{T'WH \times C} \) the representation of the \( j \)-th query clip.

As is, the query clips are separate representations, i.e., \( f^q \) only contains the spatio-temporal information within the \( j \)-th query video clip. To accurately localize the tubelets in the query video, long-term spatio-temporal information needs to be modeled. Our common attention block solves this problem. The common attention block is built on the self-attention mechanism [40] and the non-local structure [41]. The self-attention mechanism in the transformer is extended to self- and cross-attention \( \mathcal{A} \):

\[
\mathcal{A}(I_1, I_2) = \text{softmax}(\frac{Q(I_1)K(I_2)^T}{\sqrt{C}})V(I_2),
\]

where \( Q(\cdot), K(\cdot), V(\cdot) \) are linear projections. \( I_1, I_2 \) denote...
two inputs, both of which have dimension $C$. The common attention block $\hat{A}$ can be defined as:

$$\hat{A}(I_1, I_2) = I_1 + \text{Linear}(\text{LayerNorm}(A(I_1, I_2))),$$

(2)

where for simplicity, Dropout [37] and ReLU [10] operations are ignored here. A detailed overview and illustration of the common attention block is provided in the supplementary materials. As demonstrated by prior work [14, 26, 45], a self- and cross-attention mechanism can efficiently enhance a representation by itself or by other representations. In our model, the common attention block plays two important roles. In the feature extraction stage, the common attention block aligns each query clip feature with its previous clip features, making each query clip feature contain more motion information, which benefits the common action localization. In the few-shot transformer structure, the common attention block fuses the support feature into the query clip feature, making common action localization achievable.

We utilize the common attention block $\hat{A}$ to propagate the spatio-temporal information from previous clips of the query video into the $j$-th query clip for better common localization:

$$f^q_j = \hat{A}(f^q_j, f^q_{j-1}),$$

(3)

where $f^q_j \in \mathbb{R}^{TWH \times C}$ is the $j$-th query clip representation enhanced by previous clips.

3.2. Few-shot transformer

In the standard transformer, and in our few-shot transformer as well (detailed in Figure 3), the multi-head attention block is a key element. The multi-head attention block $\hat{MA}$ is built on multi-head attention $MA$ which is an extension of attention $A$:

$$\hat{MA}(I_1, I_2) = \text{concat}(A_{11}, \cdots, A_{mm})W,$$

(4)

$$\hat{MA}(I_1, I_2) = \text{LayerNorm}(I_1 + \hat{MA}(I_1, I_2)),$$

(5)

where $m$ denotes the number of heads, $W$ denotes a linear projection, $A_{11}, \cdots, A_{mm}$ are parallel instances of $A(I_1, I_2)$.

**Encoder.** Each encoder layer has a standard architecture and consists of a multi-head attention block $\hat{MA}$ and a feed forward network, FFN. Since the encoder architecture is permutation-invariant, we supplement it with fixed spatio-temporal positional encodings $[1, 30]$ that are added to both support video and query clip features in each encoder layer. For the support branch, we let the support video go through the encoder one by one, then concatenate the output and get a support branch input $E^s \in \mathbb{R}^{STWH \times C}$ to the decoder:

$$\hat{E}(f^s_i) = \hat{MA}(f^s_i, \text{pos}(f^s_i)),$$

(6)

$$E(f^s_i) = \text{LayerNorm}(\hat{E}(f^s_i) + \text{FFN}(\hat{E}(f^s_i))),$$

(7)

$$E^s = \text{concat}(E(f^s_1), \cdots, E(f^s_s)),$$

(8)

where $S$ denotes the number of support videos and $\text{pos}(\cdot)$ denotes the operation of adding spatio-temporal positional encoding. FFN can be seen as a 1x1 convolutional layer. For the query branch, we let the enhanced query clip feature $f^q_j$ go through the encoder and get the query branch input to the decoder $E^q = E(f^q_j) \in \mathbb{R}^{TWH \times C}$.

**Decoder.** In a standard transformer decoder there are two inputs, but in our few-shot transformer decoder there are three inputs: the support branch input $E^s$, the query branch input $E^q$ from the encoder, and the input embeddings, which are the learnt positional encodings. For the decoding, we first fuse the support feature into the query clip feature by using the common attention block, i.e. $\hat{A}(E^q, E^s)$. Then, we perform self-attention on the input embeddings via the multi-head attention block, i.e. $\hat{MA}(\text{in, in})$:

$$\hat{D} = \hat{MA}(\hat{A}(E^q, E^s), \hat{MA}(\text{in, in})).$$

(9)

The input embeddings are transformed into output embeddings by aggregating the fused feature
through another multi-head attention block:
\[
\text{out} = \text{LayerNorm}(\hat{D} + \text{FFN}(\hat{D})),
\]
which we use as representation for our final prediction.

### 3.3. Prediction network

For final prediction, a 3-layer perceptron is performed on the output embedding of the few-shot transformer, with a ReLU activation and hidden dimension $C$, followed by a linear set-based projection layer. The predicted results are the normalized center coordinates, the height and the width of the boxes w.r.t. the keyframe of the $j$–th query clip, along with the foreground/background binary labels. Just like Carion et al. [3], we use a set-based Hungarian loss [24, 38] that forces unique predictions for each ground-truth bounding box via bipartite matching. Given the clip-level common localization results, we link them over time [20] to obtain the final action tubes for the whole untrimmed query video.

### 4. Experimental setup

Existing video datasets are usually created for other vision tasks, such as classification [15, 23], temporal localization [2], action recognition [36], captioning [5], or summarization [12]. Feng et al. [7] reorganize the videos in AVA [11] (version 2.1) into a new dataset for their one-shot spatio-temporal video relocalization task, which is unsuitable for the few-shot setting of our task. To evaluate few-shot spatio-temporal common action localization, we have revised two existing datasets that come with spatio-temporal annotations suitable for our evaluation, namely AVA [11] (version 2.2) and UCF101-24 [36].

**Common-AVA.** There are 430 15-minute video clips with per-second action bounding box annotations in AVA [11]. The annotated actions cover 80 atomic action categories, including “stand”, “talk”, “listen”, etc. The actions are exhaustively annotated, covering 1.11 million action annotations with multiple labels per person. We link the consecutive bounding boxes if they have the same subject with all the action labels being the same. After linking, the tabulates with exactly the same action labels are regarded as semantically corresponding to each other. Hence, we combine multiple atomic action labels that are annotated with one bounding box together. Next, we discard the combined classes with less than 32 instances and obtain a total of 356 combined classes. We randomly select 80% of the classes for training, 10% of the classes for validation, and the remaining 10% of the classes for testing.

**Common-UCF.** UCF101 [36] is originally an action classification dataset, and a subset of 24 classes with 3,207 videos are provided with spatio-temporal annotations for action detection [36]. We use the recently revised ground truth action tube annotations from Singh et al. [34]. In UCF101-24, each action has a single class label. Among the 24 action categories in UCF101-24, 16 are used for training, 4 for validation and 4 for testing.

During training, the support videos and query video are randomly paired, while the pairs are fixed for validation and testing. Note that we do not use action class labels. More details of the two reorganized datasets are listed in Table 1.

**Implementation details.** We resize all the videos to a 320 × 320 resolution before feeding them into the backbone. The I3D model we use is first initialized by training on the Kinetics dataset [23] and then fine-tuned during the training of our model. We initialize the input embeddings by setting the values to zeros and we set its dimensionality $P$ to 10. It determines the number of predicted boxes for each keyframe. The encoder and decoder both contain 6 layers. The length of the trimmed support video is 1 second. To form a batch during the training process, the length of the query videos needs to be fixed. The query video is fixed to be 4 seconds long by randomly cropping or padding zeros in the training process. During testing, the query video in full length is fed into the model without any batching and cropping. For Common-AVA the query clip is 1 second long, as a keyframe is annotated per second in the original AVA dataset. For Common-UCF, the query clip is $\frac{1}{3}$ second long because each frame in the videos is annotated at 25 FPS. So for Common-UCF, each query clip contains 5 frames, and we treat the middle frame as the keyframe of the clip.

**Training regime.** We train our model with AdamW [27], setting the initial few-shot transformer’s learning rate to $10^{-4}$, the backbone’s to $10^{-5}$, and weight decay to $10^{-4}$. We train for 100 epochs with a learning rate drop by a factor of 10 after 70 epochs, where a single epoch is a pass over 10K training videos for Common-AVA and all training videos for Common-UCF. The batch size is set to be 12 with four Nvidia GTX 1080Ti cards.

**Evaluation metrics.** We report the frame-level mean average precision (frame-mAP) with an IoU threshold of 0.5 for both datasets. A prediction is correct when it has the cor-

Table 1: Overview of the common spatio-temporal localization datasets. Common-AVA contains a single target action per video, while Common-UCF contains videos with more action instances and longer duration.
Table 2: **Few-shot transformer ablation** on Common-AVA. The decoder achieves competitive performance by itself. It improves further when the encoder processes the support and/or query video. Best performance is obtained if the encoder processes both the support and query videos.

Table 3: **Benefit of positional encoding.** Adding spatio-temporal positional encoding to the support or query features improves performance on Common-AVA. Including it in both support and query leads to best results.

Table 4: Influence of length and number of support videos on Common-AVA. We obtain a more precise common localization with more and longer support videos.

**5. Results**

**Few-shot transformer ablation.** We evaluate the effect of the encoder and decoder in our few-shot transformer. We report results for one and five support videos in Table 2. The decoder alone can achieve common spatio-temporal localization and obtains competitive performance. Performance improves notably when we add encoder processing of either support videos or query video. We can gain 5.3 mAP increase under the one-shot setting and 6.2 mAP increase under the five-shot setting, if we let both support and query features go through the encoder.

**Benefit of positional encoding.** We report results in Table 3. Including the spatio-temporal positional encoding is always beneficial, ideally in both the support and query encoder. Not passing any spatio-temporal positional encoding to the features leads to an mAP drop of 2.3 under the one-shot and an mAP drop of 3.6 under the five-shot setting.

**Influence of support video length and amount.** Next, we ablate the effect of the length and the number of support videos on the spatio-temporal localization performance on Common-AVA in Figure 4. We sample 5, 10, 15, 20 and 25 frames for each support video and increase the support video number from 1 to 5. We find that the result gradually increases with longer support videos and/or more support videos, indicating that increasing the support information is beneficial to our modules for common action localization.

**Effect of noisy support videos.** To test the robustness of our approach, we ablate the effect of noisy inputs in the five-shot setting. Video-level noise is simulated by including noisy videos of other actions, or containing no action, in the support videos. Frame-level noise is included by not trimming the supports videos, thus several frames without common action support remain. The results are shown in Table 4. When one out of five support videos contains the wrong action, the performance drops only 1.3% from 28.1 to 26.8. Where we observe a noisy video containing no action is worse than a video containing a non-common action. When two noisy support video are from the same class, the drop is larger, which is to be expected, as this creates a stronger bias towards a distractor class. Adding a few noisy frames to the (25-frame) trimmed support videos results in slight performance drops, only when 32% of the frames in each support video are noisy, results start to suffer a bit, with a drop from 28.1 to 24.5. Overall, we find that our approach is robust to both video-level and frame-level noise for common action localization in time and space.

**Common action localization in time and space.** In this experiment we demonstrate the effectiveness of our transformer model on the task of common action localization in time and space. As the task is novel, we cannot compare with existing methods that are not designed for this task. Instead, we have adapted existing one-stage and two-stage methods, intended for other tasks. Hu et al. [14] and Kang et al. [22] provide one-stage approaches for few-shot common object de-
Figure 5: Qualitative result under one-shot (blue) and five-shot (red) settings. In the upper part are 2 sets of 5 support videos, where the leftmost video in each set is also used in the one-shot setting. For the left example of common action localization in space and time, with one support video we only miss a short piece at the end of a common action tube. When more support videos are added, we recover the missed clip. For the right example of common action localization per pixel, with one support video we can localize the common action per pixel, and we present more precise localization per pixel with five support videos.

Table 4: Effect of noisy support videos on Common-AVA for the five-shot setting. The result shows our robustness.

Common action localization in time only. This task strives to localize the temporal extent of a common action in the untrimmed query video [45]. This is a related but different task from ours. Yet, our approach is naturally extended by changing the prediction outputs from a spatial bounding box for a query video clip to a temporal bounding box for the whole query video. We compare to Yang et al. [45], Feng et al. [8] and Zhang et al. [49]. Yang et al. [45] introduce a
Table 5: **Common action localization in time and space** on Common-AVA and Common-UCF. We constructed two one-stage baselines [14, 22] and a two-stage baseline [7] from author-provided code. Our few-shot transformer obtains favourable results under the one- and five-shot settings on both datasets, without the need for proposals or other pre-defined components.

Table 7: **Common action localization per pixel** on reorganized A2D dataset. We adapted the few-shot object segmentation of Siam et al. [33] to our task. The metric is mIoU across query videos. We perform better across both settings for 3,782 videos of 43 actor-action classes. Among the 43 actor-action classes, 33 are used for training, 5 for validation and 5 for testing. The structure of our mask-head, the reorganization of Common-A2D, and the training details for common action localization per pixel are provided in the supplementary material. For comparison we adapt the few-shot common object segmentation approach by Siam et al. [33] as our baseline. We replace their flattened image feature sequences with the flattened video feature sequences. We compare to the baseline under one- and five-shot settings on Common-A2D in Table 7. Our approach performs better under both the one- and five-shot settings. In Figure 5 we also show a per-pixel segmentation result.

6. Conclusion

We consider spatio-temporal action localization in an untrimmed query video given a few trimmed support videos with a common action, without specifying the action label, temporal bounds, or spatial bounds. To tackle this challenge, we propose a few-shot transformer with a dedicated encoder-decoder structure optimized for joint commonality learning and localization prediction. Evaluation on reorganizations of AVA and UCF101-24 show that our approach localizes a common action in time and space, even when support videos are noisy. Although designed for spatio-temporal localization, our approach generalizes to temporal and per-pixel common action localization, outperforming the respective state-of-the-arts.
