ABSTRACT

In this paper, we make predictions for the behaviour of wind bubbles around young massive stars using analytic theory. We do this in order to determine why there is a discrepancy between theoretical models that predict that winds should play a secondary role to photoionization in the dynamics of H\(_2\) regions, and observations of young H\(_2\) regions that seem to suggest a driving role for winds. In particular, regions such as M42 in Orion have neutral hydrogen shells, suggesting that the ionizing radiation is trapped closer to the star. We first derive formulae for wind bubble evolution in non-uniform density fields, focusing on singular isothermal sphere density fields with a power-law index of -2. We find that a classical ‘Weaver’-like expansion velocity becomes constant in such a density distribution. We then calculate the structure of the photoionized shell around such wind bubbles, and determine at what point the mass in the shell cannot absorb all of the ionizing photons emitted by the star, causing an ‘overflow’ of ionizing radiation. We also estimate perturbations from cooling, gravity, magnetic fields and instabilities, all of which we argue are secondary effects for the conditions studied here. Our wind-driven model provides a consistent explanation for the behaviour of M42 to within the errors given by observational studies. We find that in relatively denser molecular cloud environments around single young stellar sources, champagne flows are unlikely until the wind shell breaks up due to turbulence or clumping in the cloud.

1 INTRODUCTION

Ionizing radiation from stars plays an important role in the interstellar medium. Lyman continuum photons leave the star and photoionize the gas around them in a region bounded by an ionization front, which separates this photoionized gas and the neutral gas outside. These volumes of photoionized gas are called H\(_2\)regions.

This photoionized gas recombines to neutral hydrogen over time, and hence a certain number of ionizing photons are required to keep the gas ionized. The flux of photons reaching the ionization front is also reduced by a geometric dilution factor, which describes the fact photons leaving the surface of a star in radial directions are spread across increasingly large spherical shells. The ionization front travels outwards if there are any remaining ionizing photons reaching the front. Since the photoionized gas is warmer (~10\(^4\) K) than the neutral gas outside (10–1000 K), this also causes thermal expansion of the H\(_2\) region. This expansion reduces the density of the photoionized gas, lowering its recombination rate and hence allowing ionizing photons to reach larger radii before being absorbed, and hence the ionization front moves outwards as the H\(_2\)region expands. The thermal expansion produces a leading shock wave that accelerates and condenses the surrounding gas into a dense shell of partially or wholly neutral gas. Models including these processes have been produced by, e.g. Kain (1954), Spitzer (1978) and Dyson & Williams (2020).

In a uniform medium with densities similar to those found in star-forming molecular clouds, the behaviour of these solutions is typically for the ionization front to move outwards rapidly over the recombination time in the gas, until none of the ionizing photons arrive at the ionization front, and so the H\(_2\)region reaches photoionization equilibrium, where the total recombination rate balances the ionizing photon emission rate from the star. The recombination time of dense gas inside molecular clouds is typically very short compared to the lifetime of massive stars that produce significant quantities of ionizing radiation. After photoionization equilibrium is achieved, the H\(_2\)region grows primarily due to thermal expansion at speeds slower than the sound speed in the photoionized gas.

However, if the ionization front moves into regions with lower gas densities, such as towards the outskirts of a molecular cloud, the outward movement of the ionization front can accelerate since the more diffuse gas is less efficient at absorbing the ionizing photons than the denser cloud material. In some cases, the H\(_2\)region leaves photoionization equilibrium and the ionization front travels outwards supersonically. This mode of H\(_2\)region evolution has been referred to as a ‘champagne’ flow by Tenorio-Tagle (1979), who invoke a step function in density to model a flow leaving a dense cloud and entering the diffuse medium outside.

\(^*\) E-mail: s.t.geen@uva.nl
Comeron (1997) produces analytic descriptions and 2D numerical simulations of such a case for a pair of massive stars embedded in the denser part of the step function, including both photoionization and stellar winds. They find that winds produce complex structures as the wind bubble enters the diffuse medium, but that their presence does not significantly affect the evolution of a rapid champagne flow driven by photoionization into the diffuse medium.

Alternatively, Franco, Tenorio-Tagle & Bodenheimer (1990) show that a champagne flow occurs if the density gradient in the neutral cloud has a power-law index steeper than $-3/2$, (i.e. one in which the density halves when the radius increases by a factor of roughly 1.6). In this mode, the Htiregion never reaches photoionization equilibrium. Simulations of star formation predict that stars are born in density peaks in clouds with a power-law index around $-2$ (e.g. Bate 2012; Lee & Hennebelle 2018), and so are likely to form champagne flows as ionizing radiation escapes the protostellar environment around the young star.

Simulations of feedback in molecular clouds with self-consistent star formation frequently reproduce such champagne flows. For example, Dale, Ercolano & Bonnell (2012), Ali, Harries & Douglas (2018) and Zamora-Avilés et al. (2019) include ionizing radiation in their simulations and report champagne flows resulting from such conditions. Ali et al. (2018) target the Orion nebula, and find some similarities with the observed region, including far ultra-violet (FUV) emission and expansion of gas above 10 km/s. Simulations including winds and photoionizing radiation from massive stars, such as Dale et al. (2014) and Geen et al. (2021) also report similar flows, with winds embedded inside them. Geen et al. (2015) find that magnetic fields can constrain the fragmentation of the shells around Htiregions and hence the escape of ionizing radiation to some extent, although even with magnetic fields, ionization radiation and warm ($\sim 10^4$ K) gas drives rapid expansion of champagne-like flows into the external medium.

However, observers such as Guedel et al. (2008) and Pabst et al. (2019) find evidence that nearby Htiregions such as the Orion Nebula are filled with x-ray emitting gas surrounded by a rapidly-expanding neutral shell. This is characteristic for stellar winds, which are emitted from the star at thousands of km/s (Lamers et al. 1993; Vink et al. 2011) and subsequently shock-heats the gas around the star to millions of degrees (e.g. Weaver et al. 1977; Dunne et al. 2003). Since the shell around this wind bubble is neutral, it implies that any ionizing radiation from the star is trapped by the stellar wind bubble. The hypothesis is that the stars in such regions are not producing champagne flows driven by ionizing radiation despite having the conditions for such flows according to the previously described theoretical models.

The purpose of this work is to use algebraic prescriptions to identify how such systems should behave and provide a stepping stone between observed behaviour of feedback structures around young massive stars, and more detailed numerical models. We apply analytic theory to power-law density fields where champagne flows can occur (e.g. Franco et al. 1990). We first give an overview of the physical systems modelled. We then derive a classical ‘Weaver-like’ solution (Weaver et al. 1977) for an expanding wind bubble in power-law density fields. In the next Section, we introduce semi-analytic and algebraic solutions for the evolution of the photoionized shell around the wind bubble and the point at which ionizing photons can overflow the neutral shell. We then discuss possible perturbations to this model, and compare our results to M42 in Orion.

The key argument of this paper is that there exists a set of solutions for a wind-driven bubble expanding into a power-law density field where the ionizing radiation remains trapped, preventing a ‘champagne’ flow as described by Franco et al. (1990). Mathematically, there is a point where this trapping should end. For typical conditions in molecular clouds around individual massive stars, our model predicts that any possible champagne flow is likely to remain ‘bottled’ by the shell around the wind bubble for the duration of the model’s applicability, unless the cloud is sufficiently diffuse. Other 3D environmental effects are more likely to allow ionizing radiation to break out from the cloud, such as nearby wind bubbles merging (e.g. Calderón et al. 2020), the density profile in the cloud flattening out as the wind expands into the wider cloud environment, or a step function to a much lower density outside the cloud as described by Tenorio-Tagle (1979).

For the rest of this Section we review the literature regarding the modelling of photoionized Htiregions with embedded wind bubbles, and lay out the structure of the rest of this paper.

1.1 Theory of stellar wind feedback

Early theoretical work by Avedisova (1972), Castor, Weaver & McCray (1975) and Weaver et al. (1977) established a basis for understanding adiabatic wind bubbles, as well as initial work on the behaviour of the bubbles in response to radiative cooling and ionizing radiation.

More recent work by Capriotti & Kozminski (2001) looked in more detail at the dynamical evolution of wind bubbles inside photoionized Htiregions, and argued that wind bubbles play a secondary role to photoionization. Haid et al. (2018) found similar results in controlled hydrodynamic simulations in a uniform medium. This was also the conclusion of Geen et al. (2020) in a power-law density field where an efficiently cooling wind bubble was invoked inside an existing photoionized Htiregion.

However, in conditions where wind bubbles retain most of their energy, they can efficiently drive expansion of hot ($> 10^6$ K) bubbles around massive stars. Whether or not wind bubbles retain most or all of the energy deposited by the star is an open question. Fierlinger et al. (2016) argue that properly resolving the contact discontinuity between the hot, diffuse wind bubble and the denser shell around it is critical in setting the energetics of the wind bubble. Gentry et al. (2017) argue that the same is true for supernovae, and that numerical diffusion in grid hydrodynamic codes can cause artificial energy losses. Fielding et al. (2020) and Tan, Oh & Gronke (2021) argue that turbulent mixing can increase the cooling rate of the wind bubble, provided the turbulence is strong enough. Increased wind pressure also increases the density of the shell around the wind bubble, more effectively trapping the ionizing radiation.

The role of radiation pressure in Htiregions has been explored in models by Mathews (1967), Krumholz & Matzner (2009), Murray, Quataert & Thompson (2010), Draine (2011) and Kim, Kim & Ostriker (2016), both with and without an embedded wind bubble. In the model of Pellegrini et al. (2007), which includes an extended wind bubble, radiation pressure further reduces the efficiency of photoionization feedback by pushing the ionized gas into a thinner shell, where it recombines faster. This analysis has been further applied to observed feedback structures around massive stars and clusters with an embedded wind bubble in Pellegrini et al. (2009), Yeh & Matzner (2012), Verdolini et al. (2013), Rahner et al. (2017) and Pellegrini et al. (2020).

How winds and radiation interact is a timely problem due to the recent inclusion of stellar winds in self-consistent (radiative-)magneto-hydrodynamic simulations of star formation on a cloud scale. Rogers & Pittard (2013) simulated stellar winds from a small cluster of O stars in an inhomogeneous cloud. Meanwhile, Dale et al.

MNRAS 509, 4498–4514 (2022)
included winds in simulations of stars forming in turbulent clouds with photoionization. Since then, Wall et al. (2019), Wall et al. (2020), Decataldo et al. (2020), Geen et al. (2021), and Grudić et al. (2021) have all included stellar winds in star formation simulations, as well as numerous other works studying winds from single sources or in idealised settings (e.g. Gallegos-Garcia et al. 2020) or on larger scales (e.g. Agertz et al. 2013; Gatto et al. 2017). To facilitate further development of such studies, more careful work is needed to determine whether simulations properly resolve the interaction between winds, radiation and star-forming clouds.

Simulations of stellar winds are significantly more expensive than simulations with just photoionization due to the characteristic speeds and temperatures, and the subsequent effect on the simulation timestep. The sound speed in photoionized gas is typically 10 km/s (e.g. Oort & Spitzer 1955), whereas stellar winds have a terminal velocity of up to around 1 per cent of the speed of light (Groenewegen, Lamers & Pauldrach 1989; Lamers et al. 1993; Howarth et al. 1997; Massey et al. 2005). Given this, careful work is required to explore the parameter space of the influence of winds, and ensure that simulations accurately capture the interaction between each of the processes that occur inside a star-forming cloud. For example, in Geen et al. (2021), it was noted that the behaviour of the wind bubble had some differences with the Orion nebula described in Pabst et al. (2019), although there were similarities between the conditions in the two systems. Establishing a firm basis for feedback physics requires a convergence between complex and costly numerical simulations and observations, for which analytic theory is a valuable stepping stone.

2 OVERVIEW

The goal of this paper is to describe the behaviour of feedback structures around young massive stars. Initially, we invoke a wind bubble around the star expanding in a power-law density field. Since the medium is dense, it traps ionizing radiation initially, which forms a thin photoionized layer inside the dense neutral shell swept up around the wind bubble. This is reasonable because as authors such as Kuiper & Hosokawa (2018) find, the initial protostellar outflows around stars are not driven by photoionization, so it follows that a pre-existing shell trapping ionizing radiation can form.

As the dense shell expands, the fraction of the shell that is photoionized becomes larger, until the whole shell is photoionized. After this point, the ionizing radiation overtakes the shell around the wind bubble and causes an ‘overflow’ of ionizing radiation into the surrounding medium, beginning a ‘champagne flow’ that rapidly photoionizes the unperturbed neutral gas outside.

We aim to describe (i) the early evolution of the wind bubble in a power-law density field, (ii) the point at which ionizing radiation overflow occurs, and (iii) identify where other effects not included in the main model lead to the requirement for more complex semi-analytic or numerical models.

In Fig. 1, we show a schematic for the structure of the shell around the wind bubble prior to overflow. The inside of the wind bubble is shock-heated to a high temperature by the energy from winds injected at high velocity by the star. Weaver et al. (1977) describes the internal structure of this wind bubble, which includes a ‘free-streaming’ region in the centre of the wind bubble where the material from the wind travels outwards at supersonic speeds before shocking against the gas inside the bubble and creating temperatures $> 10^6$ K. We return to the internal structure of the bubble later in the paper where we discuss radiative cooling, but for most of this paper it is only relevant that the bubble is a hot adiabatic volume of gas.

The interior of the wind bubble is collisionally ionized, and hence the flux of ionizing radiation from the star is not noticeably depleted until it encounters the inner edge of the dense shell around the wind bubble at $r_w$ and begins photoionizing the gas there. Between $r_w$ and $r_i$ there is a thin photoionized shell. This gas has a temperature of roughly $10^5$ K, determined by the equilibrium of cooling and heating of the photoionized gas.

In the absence of radiation pressure, this region has a uniform density and is supported by thermal pressure alone. With the inclusion of radiation pressure, there is a pressure differential inside the region due to the larger surface area at larger radii and the presence of dust.
Finally, between \( r_l \) and \( r_s \), there is a cold, dense neutral shell of material swept up by the wind bubble. At the point of overflow, the quantity of the shell that remains neutral tends to zero, at which point ionizing radiation can enter the neutral power-law density field outside.

We note that this picture applies for steeper power-law density fields as found around young massive stars. In uniform density fields, Cameron (1997) and Silich & Tenorio-Tagle (2013) note that overflow becomes less possible the larger the wind bubble becomes. They argue that as a shell around the wind bubble grows, the H\(_2\) region reaches a ‘trapping’ point where ionizing radiation emitted by the star becomes trapped by the shell around the wind bubble. For much of this paper we thus adopt a fiducial ‘singular isothermal sphere’ density field with a power-law index of \(-2\), which is typical for the conditions around very young massive stars sitting in star-forming cores that have just ended the protostellar phase and is adopted by other authors such as Shu et al. (2002).

The models in this paper also allow for a wind bubble that is completely constrained by dense gas along certain lines of sight, as in a blister region or a case where outflow occurs only in a small solid angle around the star. In this case we invoke a solid angle subtended by the wind bubble \( \Omega \), which tends towards \( 4\pi \) as the wind bubble expands in all directions into a spherically symmetric density field.

### 2.1 Initial environment around the star

Due to the large parameter space of possible environments into which feedback from young stars can evolve, we confine ourselves to a set of physically motivated quasi-1D models for the conditions for young massive stellar objects in star-forming cores. A similar analysis can be applied to other conditions, such as a moving source or a density step function for flows breaking out of a denser cloud environment.

We define the young massive star as sitting in a cold neutral distribution of gas with a spherically symmetric power-law density distribution given by

\[
n(r) = n_0 (r/r_0)^{-\omega}
\]

where \( n(r) \) is the hydrogen number density at a radius \( r \), \( n_0 \) is the density at \( r_0 \) and \( \omega \) is the power-law index. \( \omega = 0 \) gives a uniform density field, and \( \omega = 2 \) is described as a singular isothermal sphere.

We consider this distribution over an open angle \( \Omega \), with a maximum value of \( 4\pi \) if the density distribution extends across all lines of sight. Smaller values can be found if much denser gas constrains the bubble along certain lines of sight. The mass enclosed in radius \( r \) in the initial conditions is thus

\[
M(<r) = \int_0^r \Omega r'^2 n(r') m_H X \, dr' = \frac{\Omega}{3-\omega} n_0 r_0^{3-\omega} \frac{m_H X}{X}
\]

where \( m_H X \) is conversion factor from hydrogen number density to mass density, and \( X \) is the hydrogen mass fraction in the gas. We also define a characteristic mass density \( \rho_0 \equiv n_0 m_H X \).

Franco et al. (1990) use this distribution above a threshold ‘core’ radius of \( r_c \), which defines the edge of the protostellar core. For \( r < r_c \) they assume that the density is constant, approximating a protostellar core. For the sake of simplicity, we neglect this core radius in further calculations in this paper. We justify this by noting that simulations of protostellar core formation by Lee & Hennebelle (2018) find radii where the density profile begins to flatten at radii of around 20 AU \( \approx 10^{-4} \) pc. This is much smaller than the scales studied here (on the order of parsecs).

However, the presence of a small core at the point the star is formed remains an important ‘initial condition’ in our assumptions due to the fact that in a pure power-law density field, ionizing radiation would quickly photoinitize the whole cloud as in Franco et al. (1990). We also note that in reality, main sequence stellar feedback is preceded by feedback from protostellar outflows, where photoinization is a secondary process (Kuiper & Hosokawa 2018). Therefore, in a realistic physical context, winds and ionizing photons from the star will be emitted into a medium initially preprocessed by a kinetic outflow rather than a pristine neutral gas field.

### 2.2 Stellar models

Throughout this work, we use the same stellar evolution tables as Geen et al. (2021). These are based on Ekström et al. (2012) for the stellar parameters, using Leitherer et al. (2014) to give the stellar spectra and a correction from Vink et al. (2011) to convert the escape velocity of the star into a wind terminal velocity. Relevant physical values for each star are listed in Appendix C and Tables C1 and C2.

### 3 STELLAR WIND BUBBLES

In this Section, we discuss the evolution of a wind bubble around a young massive star, and the role that environment plays in shaping its evolution.

#### 3.1 Revisiting adiabatic wind bubbles

Weaver et al. (1977) give a solution for the expansion of an adiabatic wind bubble in a uniform medium surrounded by a shell of swept-up interstellar gas. We now re-derive this solution for an adiabatic wind bubble expanding into a power-law density distribution, and make observations about how such systems evolve differently to the Weaver et al. (1977) solution.

The dynamical equations governing the wind bubble’s expansion are

\[
E_b = \frac{3}{2} \Omega \frac{r^3}{r_w^3} P_w,
\]

\[
\frac{d}{dr} \left( M(<r_w) \frac{d r_w}{d r} \right) = \Omega r^2 P_w,
\]

and

\[
\frac{dE_b}{d r} = L_w - \Omega r^2 P_w \frac{d r_w}{d r},
\]

where \( E_b \) is the thermal energy in the shocked gas inside the wind bubble and \( P_w \) is the pressure from the wind bubble acting on the inside of the shell. Equation (4) describes the conservation of momentum, and equation (5) describes the conservation of energy. The first term on the right hand side of this latter equation, \( L_w \), is the wind luminosity of the central source, i.e. the mechanical power of the material ejected by the star, assumed constant here for simplicity. The second right hand side term is the work done by the gas pressure \( P_w \). The temperature and density of the wind bubble are not immediately important in deriving this solution. We give estimates for these quantities in Section 5.3.

To solve these equations, we require the energy stored inside the wind bubble, which is the fraction of energy emitted by the star not used to do work on the shell around the wind bubble. We derive a quantity for this in Appendix A, which is given by

\[
E_b = \frac{5 - \omega}{11 - \omega} L_w t
\]

where \( t \) is the time since the onset of the wind.
To produce a tractable solution, we further assume that \( r_w(t) \propto t^\beta \), where \( B \) is some power-law index. Solving for these equations plus equation (2), we find

\[
r_w(\omega, t) = \left( \frac{A_w(\omega, \Omega) \rho_0}{10^6 \text{ erg/s/cm}^3} \right)^{1/3} \left( \frac{n_0}{1000 \text{ cm}^{-3}} \right)^{-1/3} \left( \frac{t}{1 \text{ Myr}} \right)^{1/3}
\]

(7)

where

\[
A_w(\omega, \Omega) = 4\pi \left( \frac{1 - \omega/3}{1 - \omega/5} \right) \frac{250}{\Omega} \left( \frac{1 - 2\omega/7}{1 - \omega/11} \right) 308\pi
\]

(8)

This becomes the ‘Weaver’ solution (equation 21 of Weaver et al. 1977) if \( \Omega = 4\pi \) and \( \omega = 0 \). We verify equations (6) and (7) using simple 1D hydrodynamic simulations in Appendix B, and find good agreement.

For \( \omega = 2 \) and \( \Omega = 4\pi \), equation (7) becomes

\[
r_{w,2}(t) = 13.9 \text{ pc} \left( \frac{L_w}{10^6 \text{ erg/s}} \right)^{1/3} \left( \frac{n_0}{1000 \text{ cm}^{-3}} \right)^{-1/3} \left( \frac{t}{1 \text{ Myr}} \right)^{1/3}
\]

(9)

which has a constant expansion velocity

\[
v_{w,2} = 13.5 \text{ km/s} \left( \frac{L_w}{10^6 \text{ erg/s}} \right)^{1/3} \left( \frac{n_0}{1000 \text{ cm}^{-3}} \right)^{-1/3}.
\]

(10)

This is a useful result for the regions immediately around young massive stars, where stars typically form in cores where \( \omega \approx 2 \) as matter accretes on to the site of protostar formation. (e.g. Lee & Hennebelle 2018). At larger radii where this steep profile merges into the cloud background, we expect the solution to become more Weaver-like again, or breakup due to clumping and turbulence in the cloud. Where this happens depends on the specific environment around the star.

### 3.2.2 Dependence on stellar mass, metallicity and cloud density

In Fig. 3 we plot the dependence of the wind bubble expansion rate \( v_{w,2} \) in equation (10) (i.e. for a power-law density profile where \( \omega = 2 \)). Wind luminosity increases with stellar mass and metallicity, giving faster expansion rates. Meanwhile, the expansion rate drops with increasing characteristic density. We include this figure as a quick visual reference for physically relevant conditions.

### 4 EXPANSION AND OVERFLOW OF THE PHOTOIONIZED SHELL

The dense shell swept up by the wind bubble interacts with the ionizing radiation emitted by the star, and contains an ionized and a neutral component (see Fig. 1). In this Section we use the results of Section 3 to calculate the structure and evolution of the photoionized component of the shell, determine at which point the dense shell cannot absorb all of the ionizing radiation from the star, and discuss what happens after this point.

#### 4.1 Structure of the Ionized shell

The dense, wind-swept shell is typically dense enough that the recombination time of the gas is short, and hence we assume photoionization equilibrium, i.e. the photons emitted by the star in the solid angle of the shell are all absorbed by the shell. We can write the balance of photon emission and absorption as

\[
\frac{\Omega}{4\pi} Q_H = \int_{r_w} r^2 n_i(r) a_{\alpha B} dr
\]

(11)

where \( Q_H \) is the ionizing photon emission rate, \( n_i(r) \) is the hydrogen number density in the photoionized gas at a radius \( r \) and \( a_{\alpha B} \) is the Baker & Menzel (1938) case B recombination rate of the gas for H\( \alpha \), which is 2 to 3 \( \times 10^{-13} \text{ cm}^3 \text{s}^{-1} \) at solar metallicity. The exact formula used to calculate \( a_{\alpha B} \) depends on the temperature of the photoionized gas and is given in Appendix E2 of Rosdahl et al. (2013).

Equation (11) has an algebraic solution if either (i) the shell is sufficiently thin that \( r_w \rightarrow r_w \), or (ii) the density of the photoionized shell is uniform, i.e. \( n_i \) is independent of \( r \). Case (i) becomes valid when photoionization is negligible compared to radiation pressure and winds and case (ii) becomes valid when radiation pressure is negligible. A more general solution, however, requires a numerical approach.

Numerical solutions for photoionised shell structures have been used widely in the literature to calculate the dynamical and observable properties of photoionized shells, e.g. Pellegrini et al. (2007), Yeh & Matzner (2012) and Kim et al. (2016). A form of these equations is given in Draine (2011) for dusty HII-regions, which was used by Martínez-González, Silich & Tenorio-Tagle (2014) to include a central wind bubble. Draine (2011) gives the...
Figure 2. Expansion rate of the wind bubble with time around an example star to demonstrate the role of environment. The left panel shows the density field power-law index \( \omega \), which describes how steep the density around the star is. The right panel shows the solid angle that the wind bubble expands into, \( \Omega \), where \( 4\pi \) describes a full sphere with the star at the centre. In the left panel, we fix \( \Omega = 4\pi \), and in the right panel we fix \( \omega = 2 \). For both panels we use a star of mass \( 35 \, M_\odot \), \( n_0 = 4000 \, \text{cm}^{-3} \) and \( r_0 = 1 \, \text{pc} \).

Figure 3. Expansion rate of the wind bubble as a function of stellar mass and characteristic background density \( n_0 \) at 1 \, \text{pc} where \( \omega = 2 \) and \( \Omega = 4\pi \). Solid lines show results at a Solar metallicity \( Z = 0.014 \), and dashed lines the results at a sub-Solar metallicity \( Z = 0.002 \). This expansion rate is constant with time such that \( r_{\text{w},2}(t) = v_{\text{w},2} t \). Winds are weaker in the sub-Solar case and so the bubble expands more slowly.

We solve these equations beginning at \( r_\text{w} \), where the density \( n_i \) is set by the pressure balance with the wind bubble,

\[
P_w = P_i \equiv \frac{m_H}{X} n_i c_i^2
\]

(e.g. Dyson & Williams 2020), where \( P_w \) is given in equation (5). We integrate for increasing \( r \) until \( \phi \) reaches zero, i.e. all the ionizing photons have been absorbed, which we define as the edge of the photoionized shell \( r_i \).

For each value of \( r_w \) we use, we calculate the mass of the photoionized shell

\[
M_i = \int_{r_w}^{r_i} \frac{\Omega r^2 n_i(r) m_H}{X} \, dr,
\]

and compare it to the total mass of gas swept up by the Htregion out to \( r_i \), \( M(< r_i) \) using equation (2). If the value found for equation (16) exceeds \( M(< r_i) \), the solution breaks down because there is no more mass in the neutral shell to absorb the ionizing photons. We refer to this stage of the solution as ‘overflow’, since ionizing photons are able to overflow the shell. We discuss the consequences of this later in this Section.

4.2 Numerical solutions for shell structure and overflow

In this section we plot a set of solutions to the equations in Section 4.1. In order to provide a tractable subset of the parameter space of possible inputs, we focus on cases where \( \omega = 2 \) for a set of physically-motivated conditions. As in Section 3.2, we use values from Table C1 for the stellar properties. For these solutions, we require \( Q_H, L_\odot, L_i \equiv Q_H/(hv)_i, T_i \) and \( L_w \). The latter quantity is used to calculate \( r_w \), which is the inner boundary of the photoionized shell. We use fiducial
Point at which ionizing photon overflow occurs as a function of initial stellar mass, with varying metallicity and characteristic background hydrogen number density $n_0$, where $n(r) = n_0(r/1 \, \text{pc})^{-2}$. The left plot shows the outer radius of the ionized shell $r_i$ at which overflow occurs, the right plot shows the time of overflow. The denser the environment, the denser the shell around the wind bubble and hence the longer it takes for ionizing photons to overflow the shell. Due to weaker winds, overflow occurs sooner and at smaller radii at lower metallicity. Solid lines show results at Solar metallicity ($Z = 0.014$) and dashed lines show results at sub-Solar metallicity ($Z = 0.002$). Line colour shows characteristic cloud density $n_0$.

Densities $n_0 = 10^2$, $10^3$ and $10^4 \, \text{cm}^{-3}$, where $n(r) = n_0(r/1 \, \text{pc})^{-2}$ for the purposes of this analysis.

Fig. 4 shows the time and ionized shell radius at which the ionizing radiation overflows the shell (i.e. there is not enough mass in the shell to absorb all the ionizing radiation). There is a small dependence on metallicity, and a much larger dependence on cloud density. Note that the lifetime of the stars described here is on the order of 10 Myr, or less in the case of very massive stars. We thus expect the star to reach the end of its main sequence before overflow conditions are reached in very dense clouds. By contrast, for more diffuse clouds, overflow may occur when the star is younger. We discuss other scenarios outside the scope of the 1D model in Section 5. Nonetheless, this model suggests that, provided certain plausible initial conditions are achieved, there is a range of physically relevant conditions for which the ionizing radiation from massive stars is trapped for some or all of a star’s life, preventing a champagne flow and reducing the influence of ionizing radiation in molecular clouds.

We plot the relative thickness of the ionized shell compared to the radius of the wind bubble, $(r_i - r_w)/r_w$ in Fig. 5. This is initially small compared to the overall size of the wind bubble, growing towards the point of overflow to be similar in radius, or even larger for sub-Solar metallicities. The relative thickness is smaller for more massive stars due to the stronger winds. The relative expansion velocity of the ionized shell compared to the wind velocity $(r_i - v_{w,2})/v_{w,2}$ follows a very similar relation, having values between 1.5 and 2 times $(r_i - r_w)/r_w$. Therefore, the expansion rate of the edge of the ionized shell, where C\(^+\) emission is located, begins at around $v_{w,2}$, but can be up to $2v_{w,2}$ at the point of overflow.

The effect of radiation pressure on the structure of the ionized shell is typically small compared to the influence of winds. We can measure this by measuring the density gradient in a photoionized region around a star (Draine 2011; Martínez-González et al. 2014). If radiation pressure is non-negligible, the density should be constant with radius. This is because the pressure balance in the photoionized gas can be written as

$$P_i(r) = \rho_i(r) c_{\text{i}}^2 + P_{\text{rad}}(r),$$  \hspace{1cm} (17)

where $P_i$ is the total pressure at $r$ in the photoionized gas and $P_{\text{rad}}$ is the contribution from radiation pressure at $r$. For a hydrostatic shell, $P_i$ is constant with $r$, as is $c_i$ due to the cooling equilibrium in photoionized gas. $P_{\text{rad}}$ drops as the flux of radiation decreases over the radius of the shell due to geometric dilution and absorption by atoms and dust. Therefore, in order to maintain a constant $P_i$, $\rho_i$ must increase with $r$.

Draine (2011) measures the density contrast in a photoionized region by comparing the root-mean-square (RMS) density, the mean density and the maximum density, found at the outer edge of the region at $r_i$. The ratio between the RMS density and the mean density is negligible in all cases in our model. The maximum density is initially 1-5 percent higher than the RMS density at Solar metallicities, dropping towards smaller values for larger wind bubbles where the radiation pressure is spread across a larger surface area. For $Z = 0.002$, this difference is initially 2-13 percent, again dropping towards negligible values at larger radii. Radiation pressure can thus have a second-order effect on the structure of compact H\(\text{II}\) regions, but this importance drops at larger H\(\text{II}\) region radii towards the point of overflow.

### 4.3 Analytic description

In order to interpret the results in Section 4.2, we produce an approximate and illustrative analytic solution for the expansion of the photoionized shell that allows us to more clearly explain the behaviour of the numerical solutions to equations (12) to (14) presented in Section 4.2.

#### 4.3.1 Ionized shell structure

Our first assumption is that radiation pressure causes only a small change in $n_i$, and thus we assume a constant $n_i$, giving a solution to equation (11) that reads

$$Q_H = \frac{4\pi}{3} n_i^2 (r_i^3 - r_w^3) \Omega_B,$$  \hspace{1cm} (18)

noting the dependence on $4\pi$ and not $\Omega$ since the radiation travels in all directions, not just the solid angle subtended by the wind bubble.
Using equation (15) and substituting for $P_w$ using equations (3) and (6), we can write the number density of the photoionized gas as

$$n_i = \frac{2}{\Omega r_w^2} \left( \frac{5 - \omega}{11 - \omega} \right) \frac{X}{m_H} \frac{1}{c_i^2} \frac{L_w}{t}.$$  (19)

Substituting for $n_i$ in equation (18), we can write

$$r_i^3 = \rho^3_w + \frac{3}{4\pi} \frac{Q_H}{\alpha_B} \left( \frac{\Omega}{2} \right) \left( \frac{11 - \omega}{5 - \omega} \right) \frac{m_H}{X} \frac{c_i^2}{c_i^2} r_w^6.$$  (20)

Substituting for $t$ in equation (7), we can write this as

$$r_i = r_w \left( 1 + 3B_w r_w^{2(\omega-1)/\omega} \right)^{1/3}.$$  (21)

where

$$B_w = \pi \left( \frac{\Omega}{4\pi} \right)^2 \left( \frac{11 - \omega}{5 - \omega} \right)^2 \frac{m_H}{X} \frac{c_i^2}{c_i^2} \frac{L_w L_B}{\rho \Theta_0^2}.$$  (22)

In the thin shell limit (where $r_i \to r_w$), this equation can be written using the binomial approximation as

$$\Delta r \equiv r_i - r_w \approx B_w r_w^{2(\omega-1)/\omega}.$$  (23)

Some general comments may be made about the form of this equation. Firstly, the thickness of the ionized shell increases with $r_w$ for $\omega > 1/2$, and decreases for $\omega < 1/2$. Secondly, the thickness increases with photoionization-related quantities $Q_H$ and $c_i$ and decreases with the wind luminosity $L_w$ and characteristic background density $\rho_0$.

It is also possible to calculate the thickness of the neutral shell from the remaining swept-up mass that is not photoionized. This also requires a cooling function to calculate its density from the hydrostatic pressure in the shell, which in turn allows an estimate of the thickness, as well as including the effects of FUV radiation pressure on dust in the shell. However, we do not discuss this here since it does not affect the results of this work.

4.3.2 Condition for overflow

In order to calculate the overflow radius, we make a further simplifying assumption that the mass swept up by the shell $M(< r_i) \approx M(< r_w)$. If we do not apply this assumption, a cubic equation in $r_w$ can be found by using equation (21) that gives a similar result, although this becomes more difficult to interpret.

Since the density inside the wind bubble is typically very low, the mass in the dense shell around the wind bubble is assumed to be equal to the swept-up mass of unshocked gas at $t = 0$ in the background medium, i.e. $M(< r_w)$ using equation (2). In the limit where this mass equals the mass of the photoionized shell, all of the shell is photoionized. Beyond this point, the shell cannot absorb all of the ionizing photons, which begin leaking into the surrounding neutral gas. We can write a condition for such photon ‘overflow’ as

$$\frac{\Omega}{3 - \omega} n_0 r_w^{3-\omega} m_H \frac{X}{X} \leq \frac{\Omega}{3} (r_i^3 - r_w^3) n_0 m_H \frac{X}{X}.$$  (24)

Making the same substitutions for $n_i$ and $t$ as in Section 4.1, we can produce an expression for the wind bubble radius at which overflow is possible, where

$$r_w \leq \frac{\Omega}{4\pi} \left( \frac{3 - \omega}{2} \right) \left( \frac{11 - \omega}{5 - \omega} \right) \frac{Q_H c_i^2}{\alpha_B} \times \left( \frac{m_H A_i^{1/2}(\omega, \Omega)}{X} \frac{L_w}{\rho_0 \Theta_0^2} \right)^{2/3}.$$  (25)

We define an overflow radius $r_o$ equal to the radius $r_w$ at the limit where overflow is just possible, i.e. the mass of the photoionized shell is exactly equal to the mass of the swept-up material.

There are again some major points to note concerning the behaviour of this equation. The right hand side increases for larger
values of \( Q_H \) and \( c_i \), and decreases for larger values of \( L_w \) and \( n_0 \). However, the left hand side behaves differently depending on the value of \( \omega \). For \( \omega < 5/4 \), as in an initially uniform density field where \( \omega = 0 \), overflow becomes less likely with increasing radius, assuming a dense shell can accumulate at \( r_w \) rather than being dispersed by hydrodynamic mixing. This model is described in Comeron (1997) and Silich & Tenorio-Tagle (2013), who argue for a ‘trapping’ radius, where ionizing radiation initially forms an extended photoionized region, but over time a wind shell grows in the warm photoionized medium at \( r_w \) until its density and mass are sufficient to trap the radiation.

However, for a power-law density field above this value, such as where \( \omega = 2 \), the left hand side decreases with radius, and so overflow becomes more likely as the wind bubble grows.

This is important because for a wind bubble around a young massive star expanding into a deep power-law density field there exists a family of solutions for which the ionizing radiation cannot escape until some overflow radius. This requires that the initial conditions are such that an instant champagne flow as described by Franco et al. (1990) is prevented, e.g. by a small shallow core in the density profile around the star or an initial shell set up by protostellar outflows that can trap ionizing radiation during the main sequence stage of the star’s evolution. If these conditions are met, this offers a plausible explanation for why we observe some young HII regions that do not exhibit photoionized champagne flows, such as M42 in Orion (Pabst et al. 2019), and rather appear to be filled with hot, wind-shocked gas (Guedel et al. 2008) and are surrounded by neutral shells (Pabst et al. 2020).

In the following Section, we discuss perturbations to the model from other physical effects, and cases where photon escape may be possible before the overflow radius is reached.

4.4 Post-Overflow conditions

Reaching the overflow radius does not guarantee an immediate and strong champagne flow. Firstly, just after the point of overflow, while the neutral shell and any observational tracers from it disappear, only a small number of ionizing photons will leak into the surrounding medium, causing only a weak decoupling of the thermally-expanding HII region and ionization front. Initially, the shell does not respond to the change in conditions outside. However, as the rarefaction wave that moves backwards from \( r_i \) approaches \( r_w \), pressure gradients will cause the shell around the wind bubble to begin to be dispersed into the surrounding medium. Under these conditions, the recompression rate in the shell drops and more ionizing photons can leak, causing the shell to disintegrate and a strong champagne flow to begin. This will likely be enhanced if discontinuities in the cloud density are encountered, e.g. as the shell reaches a sharp step in density between the molecular cloud and the diffuse interstellar medium around it, as in Tenorio-Tagle (1979), or if clumping in the cloud breaks up the wind-driven shell. Under these conditions, the wind bubble will likely rapidly break out of the cloud in an unstable plume as found in Comeron (1997) and Geen et al. (2021).

For very massive stars in diffuse molecular clouds, the wind bubble can expand much faster than the speed of sound in the photoionized gas, so under these conditions the wind bubble can expand more rapidly than the gas can expand thermally after it is photoionized, preventing a strong champagne flow. The precise behaviour of the HII region after it reaches the overflow radius is mostly beyond the scope of this paper, since we primarily wish to explain why certain HII regions appear to retain neutral shells that suggest they precede the emergence of a champagne flow. We thus leave a more detailed description of the post-overflow dynamics for future work.

5 DISCUSSION

In this Section we discuss effects neglected so far in our model, and the impact they may have on the solutions.

5.1 Magnetic fields

In this paper so far we have neglected magnetic fields. We now discuss their likely effect on the evolution of the shell around the wind bubble.

We can modify equation (15) to include a term to describe the magnetic pressure in the shell. We then get

\[
P_w = \frac{m_H}{\rho} n_i(r_w) c_i^2 + \frac{B^2}{8\pi},
\]

(26)

where the first term of the right hand side is the thermal pressure of the inner edge of the shell \( P_{\text{thern}} \) and the second is the magnetic pressure \( P_{\text{mag}} \).

To get an estimate of the likely magnetic field in the shell, we use an approximation to Crutcher (2012) and assume a critical B-field, where

\[
\left( \frac{B}{10 \mu G} \right)^2 = \frac{n_i(r_w)}{300 \text{ cm}^{-3}}
\]

(27)

in the regime studied here. The magnetic field saturates at 10 \( \mu \)G below 300 \( \text{cm}^{-3} \), equation (26) then becomes:

\[
P_w = \frac{m_H}{\rho} n_i(r_w) c_i^2 + (10 \mu G)^2 \frac{n_i(r_w)}{300 \text{ cm}^{-3}}.
\]

(28)

The plasma beta \( \beta \equiv P_{\text{thern}}/P_{\text{mag}} \) of the ionized shell assuming \( c_i \approx 10 \text{ km/s} \) is 169. The pressure from magnetic fields is thus under 1 per cent of the thermal energy, and so we justify neglecting it for the rest of the calculations in the paper. The importance of magnetic fields is likely instead to be prevent the fragmentation of the shell and other gaseous structures, as found in Hennebelle (2013) and Geen et al. (2015). Models taking into account geometry effects on the magnetic field may also lead to a non-negligible role in shaping the photoionized shell, as discussed in Pellegrini et al. (2007).

5.2 Gravity

We have until now ignored gravity in our model. The pressure from gravity on a spherical shell of inside \( r_i \) is given by

\[
P_{\text{grav}} = \frac{GM(<r_w)^2}{4\pi r_i^4}
\]

(29)

We calculate \( P_{\text{grav}}/P_w \) at the point of overflow for the same conditions as Fig. 4 and plot it for various stellar masses and densities in Fig. 6. Gravity has only a small effect at low densities, high metallicities and large stellar masses. Only for the highest densities and lowest stellar masses does gravity become comparable to the pressure from winds. We therefore justify ignoring it for this work, although in certain regimes, particularly if wind cooling becomes efficient and hence \( P_w \) drops, it may act to compress the shell or even stall the expansion of the HII region.

For regimes such as older HII regions around massive clusters, gravity has been found to be more important where the pressure inside the bubble has begun to drop due to expansion and radiative cooling (e.g. Rahner et al. 2017).
where $n_0$ at 1 pc where $\omega = 2$. Gravity is more important in denser environments, but typically does not overcome the pressure inside the wind bubble for this range of densities. A horizontal grey line shows the point where $P_{\text{grav}} = P_w$.

5.3 Radiative cooling

In this section we discuss the role of radiative cooling on the wind bubble. To do this, we adopt a similar approach to Mac Low & McCray (1988). The total energy loss rate from cooling inside the wind bubble can be written as

$$\frac{\text{d}E_{\text{cool}}}{\text{d}t} = \int_0^{r_{\text{lin}}} n_0^2(r) \Lambda(T_b(r), Z) \Omega r^2 \text{d}r$$

(30)

where the cooling function in the range being considered is given by

$$\Lambda(T_b(r), Z) = 10^{-22} \text{erg cm}^{-3} \text{s}^{-1} \left( \frac{T_b(r,t)}{10^6 \text{K}} \right)^{7/10} \times \left( \frac{Z}{Z_{\text{olar}}} \right),$$

(31)

and $T_b(r)$ and $n_0(r)$ are the temperature and hydrogen number density inside the wind bubble as a function of $r$ (distinct from the external density profile $n(r)$), and $r_{\text{lin}} \rightarrow r_w$ is the radius inside which the cooling is considered. Weaver et al. (1977) gives the temperature inside the bubble as

$$T_b(r,t) = \left( \frac{P_w r_w^2}{T_c} \right)^{2/7} \left( 1 - r/r_w \right)^{2/5} = T_c (1 - r/r_w)^{2/5},$$

(32)

where $T_c$ is the temperature at the centre of the bubble and $T = 6 \times 10^{-7} \text{ erg s}^{-1} \text{ cm}^{-3} \text{ K}^{-7/2}$. Using the ideal gas equation $P_w = n_0(r) k_B T_b(r)$ together with equations (3) and (6), we can find a similar expression for $n_0(r)$,

$$n_0(r,t) = \left( \frac{P_w r_w^2}{k_B} \right)^{2/7} \left( 1 - r/r_w \right)^{2/5} = n_s(t)(1 - r/r_w)^{-2/5},$$

(33)

where $n_s$ is the particle density at the centre of the bubble.

Since these equations create a singularity in equation (30) at $r_w$, Mac Low & McCray (1988) pick $r_{\text{lin}} = r_w (1 - (T_{\text{crit}}/T_c)^{2/5})$ where $T_{\text{crit}} = 10^7 \text{ K}$, arguing that below this temperature the cooling function $\Lambda$ changes shape. In addition, if the wind bubble cooled down to $10^4 \text{ K}$, it would reach temperature equilibrium with the photoionized shell outside.

Since $r_{\text{lin}}$ is a function of $T_c$, we do not give a fully algebraic solution to equation (30), but instead plot solutions for it as a function of time in the case where $\omega = 2$ in Fig. 7.

We find that for all cases studied, the cooling rate from the wind bubble is 1 per cent of the wind luminosity or lower, dropping over time as the bubble expands into a lower-density environment, and as such this cooling channel should not affect these calculations.

There are a few other cooling channels that can become significant. Fierlinger et al. (2016) invoke thermal conduction across the wind bubble interface, as do Gentry et al. (2017) and El-Badry et al. (2019) for supernova remnants. Correct thermal transfer across the contact discontinuity between the wind bubble and the (photoionized) shell is crucial in determining the energy budget of the wind bubble. Further, Fierlinger et al. (2016) argue that cooling in the outer part of the shell as it shock heats against the dense gas should be correctly treated to account for artificial numerical mixing. Turbulent mixing can also be important under the conditions described in Tan et al. (2021).

Under these conditions, fractal effects on the structure of the wind shell can lead to enhanced cooling (Lancaster et al. 2021, see also Fielding et al. 2020), causing a momentum-driven wind bubble with negligible thermal pressure (Silich & Tenorio-Tagle 2013).

One other cooling mechanism is described in Arthur (2012), who performed 1D spherically-symmetric hydrodynamic simulations using a uniform external density distribution. They find hotter gas in simulations than is observed in regions such as the Orion Nebula. They argue that the evaporation of dense embedded protoplyds (protoplanetary disks affected by feedback) causes mixing with the hot wind bubble, cooling it and slowing its expansion.

We caution that the cooling rate of the wind bubble is very sensitive to the ability for the hot bubble to mix with the cooler, denser gas outside the bubble. More careful hydrodynamic simulations of this phenomenon are needed to constrain the role of cooling further.

5.4 Gravitational shell instability

Ionizing photons can escape if instabilities in the shell cause it to breakup sufficiently for low-density channels to form. Gravitational instabilities provide one such channel. For a wind shell moving through a uniform medium ($w = 0$), Elmegreen (1994) give the following condition for gravitational instabilities:

$$\frac{\pi G \rho_0}{3 c_s} > \frac{8^{1/2} v_0}{r_w^2}$$

(34)

where $c_s$ is the sound speed in the neutral shell and $v_0$ is the speed of the shell in the uniform medium. In this case, the column density of the shell $\sigma_0 = \rho_0 r_w / \beta$. For a $\omega = 2$ profile, we can use equation (2) to give a column density of the shell $\sigma_2 = \rho_2 r_w^2 / r_w$. Modifying this equation to use the new column density, we arrive at a limiting velocity for instabilities of $v_{\text{inst}} = \pi G \rho_0 r_w^2 / \frac{8^{1/2} c_s}{r_w}$

(35)

where $v_{w,2} < v_{\text{inst}}$ for instability to occur. This gives $v_{\text{inst}} \simeq (n_0/1000 \text{ cm}^{-3}) \text{ km/s}$ for $c_s = 0.2 \text{ km/s}$. This is much lower than typical values for $v_{w,2}$ except for the lower mass stars studied here, as in Fig. 3, where it is still at least an order of magnitude lower.

Thus we do not expect the wind bubble to experience gravitational instabilities before other forms of photon breakup occur. We further discount Rayleigh-Taylor instabilities since the shell is not accelerating, although even if it were, the growth rate would typically be small compared to the timescales studied in Section 4.
However, this does not discount other forms of instability or interactions with clumps and other aspherical structures in the surrounding medium triggering some form of breakup. There remains a crucial role for detailed 3D hydrodynamic simulations to explore such behaviour.

5.5 Application to Orion

Recent observations of nebula M42 in Orion, henceforth referred to as the Orion Nebula, suggest that it is a wind-driven bubble with a neutral shell travelling at 13 km/s with a derived age of 0.2 Myr (Pabst et al. 2019, 2020). The fact that the shell contains neutral gas implies that the shell traps ionizing radiation from the source star, since otherwise the shell would be photoionized. In this section we apply our model to the region to determine whether we predict this behaviour.

The nebula is powered by the O7V star θ1 Ori C. This star has an evolutionary mass of 33 ± 5 M⊙ (Balega et al. 2014; Simón-Díaz et al. 2006). The star is situated close to a dense filament and the nebula is expanding away from the star out to a distance of 4 pc (Guedel et al. 2008) in a roughly circular shape on the sky, with the source star near the edge of the nebula. We assume for the purposes of this work that the wind bubble is expanding rapidly into a ω = 2 density field, since this is similar to what we find in simulations of young massive stars in clouds similar to this region (Geen et al. 2021).

We adopt two models for the initial geometry of the region for the purposes of calculating solutions to the equations in Sections 3 and 4, illustrated with a schematic in Fig. 8. In the first model, the initial gas mass distribution is centred in the middle of the nebula, with a radius of 2 pc and solid angle subtending the whole sphere around the centre, Ω = 4π. This model is used by authors such as Arthur (2012), who invoke an HII region expanding into a uniform medium.

In addition to this model, we adopt a second model. This is because the position of the star is not at the centre of the nebula, but at one edge bounded by denser gas that constrains the nebula in that direction (see Fig. 8). To better capture this view of the region, the second model places the star at the corner of a conic section of opening angle π, reaching out to 4 pc at the edge of the nebula.

Both models adopt a ω = 2 density profile. We consider this to be relatively unlikely in the first model since the remaining neutral dense gas and star are to one edge of the nebula, although we include it for the purposes of comparison with uniform background models in the literature that invoke a spherically symmetric solution with radius 2 pc.

Since the star is rotating only at a few per cent of critical velocity (Simón-Díaz et al. 2006), we use the non-rotating Geneva tracks to model the region (Ekström et al. 2012), with stellar spectra obtained from Starburst99 (Leitherer et al. 2014) (see Table C2). We give solutions from the 30 and 35 M⊙ tracks to provide estimates of the uncertainty induced by variations in the stellar evolution model for the star.

Pabst et al. (2020) derive from observations masses for the shell around the Orion Nebula between 600 and 2600 M⊙ (or up to 3400 M⊙ with the upper bound on errors given in Pabst et al. 2019), with an expected value of 1500 M⊙. The uncertainty depends on the method used to calculate the shell mass and which parts of the shell are considered. In this mass range, $n_0 = 1921 \pm 1200$ cm$^{-3}$ if $\Omega = 4\pi$ and $n_0 = 3842 \pm 2400$ cm$^{-3}$ if $\Omega = \pi$.

From this mass range, we can use equation (2) to find $\Omega n_0 r_o^2$. We use these values as inputs to our semi-analytic model in Section 4 for the shell evolution. Since the C$^+$ emission measured by Pabst et al. (2020) comes from the part of the shell after $r_i$, we use $r_i$ and $dr/dt$ as the shell radius and expansion velocity, and iterate solutions to the model to find $r_{w,2}$ and $v_{w,2}$. However, we find that $r_i$ is roughly equal to $r_{w,2}$ to within a few per cent in all cases listed, so the results should be similar to if we used $r_{w,2}$ and $v_{w,2}$.

Table 1 lists the model setups used and their outcomes. All of the models give velocities and ages that agree with the Pabst et al. (2020) results to within the error given by uncertainties in the shell mass used. Our preferred model, with the star situated at one end of a HII region with solid angle $\Omega = \pi$, predicts a slightly older region of around 0.3 Myr, expanding around 1-2 km/s faster, than the model.
Table 1. Table showing the results of our model for the conditions in the Orion Nebula. We follow two stellar tracks, one at $30 M_\odot$ and one at $35 M_\odot$ in order to capture the uncertainty in the stellar mass measurement for $\theta^1$ Ori C. We further adopt two models for the nebula structure, visualized in Fig. 8. In the first model, the initial gas mass distribution and the stellar wind and radiation source are centred in the middle of the nebula, with a radius of 2 pc and solid angle subtending the whole sphere around the centre, $\Omega = 4\pi$. In the second model, the nebula expands in only $\Omega = \pi$ around the star, the rest of the nebula being constrained by denser gas, with the star at the point of the conical volume and the nebula reaching out to 4 pc. We consider the second model to be more representative of the real Orion nebula, where the source of the winds and radiation is to one side of the region. For each model setup, the shell velocity $v_{r_2}$, age of the nebula $t$ and ionizing radiation overflow radius $r_{\alpha,2}$ are calculated. The error in the last three quantities comes from the uncertainty in shell mass used - see Section 5.5 for more information. The models predict that the overflow radius of the Orion Nebula is much larger than its current radius, reproducing the observed result that the ionizing radiation should be trapped by the shell around the wind bubble.

where $\Omega = 4\pi$ due to the extra time taken to travel 4 pc instead of 2 pc.

A few additional processes may affect our result. Internal cooling by proplyds as described in Arthur (2012) may reduce the overall expansion rate of the HII region. We also note that there are uncertainties in stellar atmosphere and evolution models that may affect our result, as well as uncertainties in the shell masses used that limit a more accurate velocity estimate. Nonetheless, to within the given observational errors, our model is consistent with the observed shell velocity.

The other main result of this comparison is to note that our model predicts that in all cases, the Orion Nebula has an overflow radius well above its current radius, suggesting that the ionizing radiation should be easily trapped by the shell and cause the Orion Nebula to be a wind-driven structure. The overflow radius is significantly larger in the case where $\Omega = \pi$ since the wind is compressed into a smaller volume, increasing its relative pressure and hence reducing the likelihood of overflow.

We note that the lack of 3D information in the model limits our ability to predict the exact behaviour of the shell when turbulence and instabilities occur. A better constrained model would require closer comparison to the observations, perhaps using 3D hydrodynamic simulations to account for the role of instabilities, turbulence, and other 3D effects in the system. Rather, the purpose of this work is to establish the feasibility of such behaviour of wind bubbles in trapping ionizing radiation and preventing photoionized champagne flows as observed in systems like the Orion Nebula.

There are a number of possible reasons why simulations to date do not reproduce systems behaving in this way, such as the Orion Nebula, in addition to the cooling arguments made in Section 5.3. One is that they lack the spatial resolution to properly capture the dense shell, and hence the ionizing photon trapping. Another is the role of magnetic fields, which act to prevent the breakup of extended structures in molecular clouds (Hennebelle 2013), and hence the fragmentation of feedback-driven shells (Geen et al. 2015). Finally, the precise conditions of feedback in the cloud may simply determine whether the wind bubble is surrounded by sufficient dense cloud material to prevent a breakout into the diffuse external medium. Further detailed comparison is needed to determine whether the discrepancies between conclusions from observations and numerical theory can be resolved.
6 CONCLUSIONS

In this paper, we study the expansion of wind bubbles in power-law density fields around young massive stars, with a particular focus on ‘singular isothermal sphere’ density fields \((\rho \propto r^{-2})\) as predicted to exist around young stars.

The goal of this paper is to a) derive analytic solutions for wind bubble expansion in non-uniform density fields, b) calculate at what point ionizing radiation can escape such a system and ionize the surrounding medium and c) determine at what point effects not included in this model grow to require more detailed numerical models. The reason for undertaking this study is to reconcile certain observations, which suggest feedback around young massive stars is driven principally by winds and not ionizing radiation, and theory, which has often argued that winds are not dynamically important.

We find that adiabatic wind bubbles expanding into density fields where \(\rho \propto r^{-2}\) do so at a constant rate \(v_{\text{exp}}\), which depends on the wind luminosity \(L_{\text{w}}\) and characteristic cloud density \(\rho_{0}\). Radiation pressure contributes only a small amount to the expansion of the Htregion. In denser cloud environments, ionizing radiation cannot overflow the shell around the wind bubble and escape into the surrounding medium is prevented until the shell reaches a size of several parsecs and an age of \(\gtrsim 1\) Myr. A more likely scenario is that the conditions in the external medium change to allow shell fragmentation and ionizing photon escape.

Radiative cooling, magnetic fields, gravity and instabilities do not appear to have a strong influence on the solution, although gravity can become a larger perturbation around less massive O stars in dense clouds.

Our model provides a framework for understanding the behaviour of the Orion Nebula. Our preferred model is one in which the 30-35 \(M_{\odot}\) star \(\theta^{1}\) Ori C sits at one edge of the nebula, as is observed, and the nebula expands into a singular isothermal sphere over a solid angle of \(\sim \pi\), constrained by denser gas in all other directions. Using this model, we recover an expansion velocity consistent with the observed shell velocity of 13 km/s to within the errors given by the observational studies. We also explain that the wind-driven shell should easily trap ionizing radiation under the conditions found in Orion, as observed.

The solution found in this work is likely to break down as the wind bubble enters the wider structured cloud environment. This highlights the need for detailed 3D radiative magnetohydrodynamic simulations. At the same time, sufficient resolution and care with sub-grid feedback injection recipes is crucial in correctly capturing the interaction between stellar winds, radiation and the star-forming environment. To reproduce this phenomenon, simulations should correctly capture the initial wind shell formation before a champagne flow occurs.

In summary, stellar winds around young massive stars should not be discounted from a theoretical perspective. Careful interaction between analytic theory, numerical simulations and observations are needed to determine precisely how massive stars shape their environment.

ACKNOWLEDGEMENTS

The authors would like to thank the anonymous referee for comments that helped greatly improve the manuscript. The authors would like to thank Xavier Tielens, Cornelia Pabst, and Eric Pellegrini for useful discussions during the writing of this paper. SG acknowledges support from a NOVA grant for the theory of massive star formation.

Weaver et al. (1977) divide the wind bubble into three phases. The first, from \(0 \leq r \leq R_1\), is the free-streaming stellar wind. At \(R_1\), the wind shocks against the surrounding medium, and from \(R_1 \leq r \leq R_2\) is the shocked stellar wind. Finally, from \(R_2 \leq r \leq R_3\) is the shocked interstellar material, which becomes a dense shell once radiative cooling becomes efficient and the internal pressure reduces. Due to the lower density in the region \(R_1 \leq r \leq R_2\), this volume remains roughly adiabatic until later times.

We adopt the hydrostatic approximation as in Weaver et al. (1977) for the region \(R_1 \leq r \leq R_2\) due to the typically high sound speeds and short sound-crossing times. Thus the internal pressure \(P(r, t)\) should be

\[
\frac{DP}{Dt} = 0.
\]

The continuity equation for mass is given by

\[
\frac{DP}{Dt} + \frac{\rho}{r^2} \frac{\partial (r^2 v)}{\partial r} = 0.
\]  

(A4)

This is the standard equation for mass conservation in spherical coordinates, assuming all flows occur in radial directions, where the material derivative \(D/Dt\) is defined as

\[
\frac{D}{Dt} \equiv \frac{\partial}{\partial t} + \frac{\partial}{\partial r}.
\]  

(A5)

We further invoke the energy conservation equation for the adiabatic flow

\[
D(P \gamma^{-1}) = 0,
\]

(A6)

where \(\gamma = 5/3\), i.e. the gas is monatomic.

Expanding equation (A6) gives us

\[
\frac{DP}{Dt} = \frac{\rho}{P\gamma} \frac{DP}{D\gamma}.
\]  

(A7)

and hence we can use equation (A4) to write

\[
\frac{1}{r^2} \frac{\partial (r^2 v)}{\partial r} = \frac{1}{P\gamma} \frac{DP}{D\gamma}.
\]  

(A8)

To solve the right hand side of this equation, we note that the pressure in the bubble is the energy divided by the volume, and thus \(P \propto L_w \rho c^2\). Using equation (A2), we can write

\[
P \propto \rho \left(\frac{c}{\omega}\right)^{(4+\omega)/(5-\omega)}
\]  

(A9)

and so

\[
\frac{1}{P\gamma} \frac{DP}{D\gamma} = \frac{1}{\rho c} \frac{\partial P}{\partial \rho} = -\frac{3}{4} + \omega
\]  

(A10)

Substituting this into equation (A8) and integrating, we can write

\[
v(r, t) = \int \frac{1}{r^2} \left(\frac{4 + \omega}{25 - 5\omega} \frac{r}{t}\right) dt + \frac{4 + \omega}{25 - 5\omega} r.
\]  

(A11)

By differentiating equation (A2) in \(t\), we have \(v(R_c, t) = 3R_c/5(5-\omega)t\) at \(R_c\), and so we can solve for \(f(t)\) to give

\[
v(r, t) = -\frac{11 - \omega R_c^5}{25 - 5\omega r^2 t} + \frac{4 + \omega}{25 - 5\omega} r.
\]  

(A12)

We adopt the solutions for an adiabatic wind in Weaver et al. (1977) in the region \(R_1 \ll r \ll R_c\)

\[
v \sim \frac{v_w}{4} \left(\frac{15}{16}\right)^{3/2} \frac{R_c^2}{r^2}
\]  

(A13)

Note that equation (11) of Weaver et al. (1977) contains a typo, and should read \(R_1^2\), not \(R_2^2\).
and
\[ P \sim \frac{3}{4} \left( \frac{16}{15} \right)^{3/2} \frac{v_w M_w}{\Omega R_1^3}, \tag{A14} \]
which is the wind terminal velocity, and \( M_w \) is the wind mass loss rate. The wind luminosity is given by \( L_w \equiv \frac{3}{2} M_w v_w^2 \). We also adopt a solid angle for a spherical segment \( \Omega \), which equals 4\( \pi \) for a full spherical wind bubble as in Weaver et al. (1977).

Noting the condition that \( r \ll R_c \) as in Weaver et al. (1977), we neglect the second term in equation (A12) and combine this with equation (A13) to give
\[ R_1 = \left( \frac{44 - 4\omega}{25 - 5\omega} \right)^{1/2} \left( \frac{16}{15} \right)^{3/4} \left( \frac{R_c}{v_w t} \right)^{1/2} \tag{A15} \]
Neglecting the kinetic energy in the wind bubble (since the solution is hydrostatic), the energy in the region \( R_1 < r < R_c \) is given by
\[ E_b = \frac{3}{2} \frac{\Omega}{3} \left( R_1^3 - R_c^3 \right) P(t) \approx \frac{\Omega}{2} R_1^3 P(t) \tag{A16} \]
Substituting equations (A14) and (A15) into this, we arrive at
\[ E_b = \left( \frac{5 - \omega}{11 - \omega} \right) L_w t \tag{A17} \]
which reduces to the Weaver et al. (1977) result for the case \( \omega = 0 \).

**APPENDIX B: COMPARISON WITH NUMERICAL SIMULATIONS**

In Appendix A, we re-derive the fraction of energy from the wind stored in the hot wind bubble, versus the amount used to do work on the dense shell around it, as in Weaver et al. (1977) but for a power-law density field. In this Section we verify the calculation using a numerical simulation.

The simulations were performed using VH-1,2 a freely available hydrodynamics code. We use a 1D spherically symmetric grid with radius 4 pc, subdivided into 2048 cells, numbered 0 to 2047, with identical radial thickness \( \Delta x = 403 \text{ AU} \) and employ reflective boundary conditions. The initial gas state is a power-law density field as in equation (1), with \( n_0 = 1000 \text{ cm}^{-3} \), \( r_0 = 1 \text{ pc} \), and three simulations performed with \( \omega = 0, 1, 2 \) respectively. We set the density in cell 0 to the density in cell 1 to prevent a singularity at \( r = 0 \). The temperature of the gas is set initially to 10 K everywhere, and \( \gamma = 5/3 \). No gravity, radiative transfer or radiative cooling is included.

Throughout the simulation, we inject a constant source of mass \( M_e \), momentum \( M_w v_w \) and kinetic energy \( L_w = \frac{1}{2} M_w v_w^2 \) into cell 0 directed outwards. We use \( L_w = 10^{36} \text{ erg/s} \) and \( M_w = 2.5 \times 10^{10} \text{ g/s} \), equivalent to a \( \sim 30 \text{ M}_\odot \) star. In addition to the inbuilt Courant condition in VH-1, we restrict the simulation timestep to be smaller than \( \Delta x/(100 \text{ km/s}) \), in order to ensure that the first few timesteps before the wind bubble is established are not too long. We end the simulations at 200 kyr, before the edge of the swept-up material around the wind bubble encounters the edge of the simulation volume in any simulation.

The energy in the bubble \( E_b \) is defined to be the total energy in all cells above \( 10^3 \text{ K} \), a threshold we select to distinguish between the hot wind bubble and the denser shell around it. We plot this quantity as a fraction of \( L_w t \) against time in Fig. B1 for each simulation where

\[ \omega = 0, 1, 2, \text{ and overplot the value of equation (A17) in each case. Once the wind bubble is established, the results converge towards the analytic solution. The results converge faster where } \omega \text{ is smaller. We also note that the solution in equation (A17), as with Weaver et al. (1977), makes various approximations and is not an exact solution. A full analysis of the convergence to the analytic solution, including the role of sound waves (i.e. non-hydrostatic effects), is beyond the scope of this paper.}

We additionally plot the radial expansion of the wind bubble in these simulations against the analytic solution given in equation (7) in Fig. B2, with \( \omega = 0 \) reducing to the canonical Weaver et al. (1977) solution. For the simulations, we calculate the radius of the wind bubble as being the largest radius of any cell where the temperature is above \( 10^3 \text{ K} \). There is good agreement in all cases. The radii converge

\[ \text{Figure B1. Comparison between equation (A17) and 1D numerical hydrodynamic simulations for the fraction of energy from stellar winds retained in the wind bubble, as opposed to the energy used to do work on the shell around the wind bubble. We show three simulations using initial power-law density fields whose index is } \omega = \text{ 0, 1, 2 as solid lines. Details of the simulations are given in Section B. Dashed lines show the value of equation (A17) in each case. This figure shows that the energy fraction in the wind bubble converges to the analytic solution.}

\[ \text{Figure B2. Comparison between equation (7) and 1D numerical hydrodynamic simulations for the radius of the wind bubble, using the same simulations and line styles as in Fig. B1.} \]
around 100 kyr, although the expansion rates are still somewhat different.

APPENDIX C: STELLAR PROPERTIES

We give the stellar properties used in this paper in Table C1 for rotating stars, and C2 for non-rotating stars. For simplicity, in this paper the values are taken to be constant throughout the star’s lifetime, using the values at a stellar age of 10^7 years. Stellar properties are taken from the Geneva stellar evolution models (Ekström et al. 2012), with atmospheres calculated using STARBRUST99 (Leitherer et al. 2014). Wind luminosities are calculated by converting the surface escape velocity of the star into terminal velocity \(v_e\) using the prescription described in Gatto et al. (2017). Further detailed descriptions of the techniques used to calculate the stellar models and plots of the evolutions of these properties at late times can be found in Geen et al. (2021). Based on Fig. A1 of that paper, we justify our choice to use constant wind luminosities and photon emission rates by noting that these values do not change significantly for the first 1–2 Myr of the stars’ lives.

Table C1. Stellar properties used in this paper, for rotating stars (see Section 2.2). Figures outside brackets are for stars at Solar metallicity (\(Z = 0.014\)), with figures in brackets for stars at sub-Solar metallicity (\(Z = 0.02\)). \(M_{\text{init}}\) is the initial mass of the star, \(L_o\) is luminosity (i.e. mechanical power injection \(\equiv 1/2 M_e v_e^2\)) of the wind, \(M_e\) is the mass loss rate, \(L_o\) is the non-ionizing radiative luminosity of the star (photons below 13.6 eV), \(L_i\) is the total ionizing luminosity, \(Q_H\) is the hydrogen-ionizing photon emission rate and \(T_i\) is the temperature of the photoionized gas around the star (assumed to be density-independent to good approximation).
