Abstract We study statistical sum-tests and independence tests, in particular for computably enumerable semimeasures on a discrete domain. Among other things, we prove that for universal semimeasures every $\Sigma^0_1$-sum-test is bounded, but unbounded $\Pi^0_1$-sum-tests exist, and we study to what extent the latter can be universal. For universal semimeasures, in the unary case of sum-test we leave open whether universal $\Pi^0_1$-sum-tests exist, whereas in the binary case of independence tests we prove that they do not exist.

Keywords Sum-tests · Independence tests · Kolmogorov complexity

1 Introduction

At the intersection of statistics and computability theory one is interested in the most significant statistical tests satisfying certain computational restrictions. In this paper we investigate “identity testing” and tests for independence of two strings. In the traditional statistical framework one uses concrete and simple formula-based statistical tests for elementary probability distributions such as the Kolmogorov-Smirnov
test and the correlation test for Gaussian distributions. In the course of time more and more powerful tests relative to increasingly sophisticated distributions have been constructed [12, 14]. It makes sense to ask for which computational restrictions most significant tests exist.

Suppose that one wants to test a coin for fairness. A fair coin generates sequences of coin flips according to a uniform distribution. We want to test whether a generated sequence is consistent with this distribution and does not carry more structure. This is known as “identity testing” or “randomness testing”. For example, we can test whether the mean of the coin flip sequence is distributed according to a Bernoulli distribution. If the coin passes this particular test, there is still the possibility that it is tricked, but we can then go on and devise other tests. It is natural to ask whether this process of improving tests has a limit. This corresponds to the question whether there exist universal elements in a set of tests of a given complexity.

Independence testing is the process of determining whether two sources can be considered as two distinctly operating systems, or that they are part of an interacting system in which information is shared or exchanged. Such independence tests show up in many engineering applications such as source separating, dimension reduction, and noise elimination [7, 8]. In advanced practical tests [6, 13] we see an evolution of tests for more complex interactions relative to more sophisticated sources.

Identity testing has been studied for ergodic sources using universal codes in Ryabko et al. [14]. These universal codes are optimal for compressing ergodic sources and are still sufficiently computable for use in practice. The information distance and information metric introduced in [1, 11] express how similar two objects are. Complementary to independence tests, similar objects have low distance or metric value. The information metric is neither computably enumerable (c.e.) nor co-c.e. However, its computable approximations have turned out to be very useful [2, 3].

Sum-tests have been investigated as tests for randomness for finite binary strings relative to computable distributions, cf. Li and Vitányi [10]. It is shown in [10] that there are c.e. sum-tests subsuming all computable sum-tests (cf. Sect. 4 below). By considering sum-tests relative the product of two universal distributions the definition of sum-tests naturally leads to independence tests. This was first noted by Levin [9], and a more general notion was mentioned in Gács [5]. In [9] it is argued that algorithmic mutual information appears naturally as an independence test relative to two universal distributions.

We now give the formal definitions of sum-tests and independence tests. Some measure-theoretic terminology is explained along with our notation at the end of the section.

Let $P$ be a given semimeasure on the set $\omega$ of natural numbers. We call a unary function $d : \omega \rightarrow \mathbb{Z}$ with

$$\sum_{x \in \omega} P(x) 2^{d(x)} \leq 1$$

(1)

a sum-test for $P$ or simply a $P$-sum-test.1

1In [10] a sum-test is a function $d : \omega \rightarrow \omega$ rather than a function into the integers. The stricter definition is only interesting for the study of proper semimeasures $P$, that is with $\sum_x P(x) < 1$. By suggestion of
One can think of a sum-test as a test for randomness for the case of a semimeasure on a discrete domain. Namely, if $d$ is a $P$-sum-test, then for every $n$ it easily follows from (1) that the set $\{x : d(x) \ge n\}$ has weight $\le 2^{-n}$ under the semimeasure $P$. Therefore strings $x$ for which $d(x)$ is large are not random with respect to $P$.

Note that it is not really essential that sum-tests are integer functions: If we would allow them to have rational values, then since $2^{d(x)} \le 2^{[d(x)]+1} \le 2^{d(x)+1}$ we see that by rounding off $d$ upwards we would only change the sum (1) by a factor 2, not changing anything essential for the theory.

**Definition 1.1** Given two semimeasures $P$ and $Q$, a binary function $d : \omega \times \omega \to \mathbb{Z}$ with

$$\sum_{x, y \in \omega} P(x)Q(y)2^{d(x,y)} \le 1$$

(2)

is called an independence test for $P$ and $Q$.

Independence tests of this form were first studied in the PhD-research of the first author. Just as sum-tests are tests for randomness, independence tests can be thought of testing possible algorithmic dependencies between pairs of strings that are random relative to $P$ and $Q$. Note that analogously to the unary case we have that if $d$ is an independence test for $P$ and $Q$ then for every $n$ it follows from (2) that the set $\{(x, y) : d(x, y) \ge n\}$ has weight $\le 2^{-n}$ under the product semimeasure $P \cdot Q$. Therefore pairs $(x, y)$ that are random relative to $P$ and $Q$ for which $d(x, y)$ is large are not independent with respect to $P$ and $Q$.

Below we investigate to what extent there are universal (i.e. additively dominating all others) sum-tests and independence tests for a given $\Sigma^0_1$-semimeasure $P$. Our results are as follows. Let $m$ denote Levin’s universal $\Sigma^0_1$-semimeasure (cf. Theorem 3.2). First, there are no unbounded $\Sigma^0_1$-sum-tests for $m$ (Corollary 4.2), but there are unbounded and monotone $\Pi^0_1$-sum-tests for any given $\Sigma^0_1$-semimeasure (Proposition 5.1). We prove that in the following cases there is no universal $\Pi^0_1$-sum-test for $P \in \Sigma^0_1$:

- $P$ computable (Proposition 6.1)
- $P(x) = 0$ infinitely often (Proposition 6.2)
- $P$ does not have a strictly positive computable lower bound, i.e. a computable $Q$ such that $P(x) \ge Q(x) > 0$ a.e. $x$ (Corollary 6.3)

Note that no universal $\Sigma^0_1$-semimeasure satisfies any of these. The most important question we leave open is whether for $P = m$ there is no universal $\Pi^0_1$-sum-test (Question 6.4). In Sect. 7 we answer this question in the binary case of independence tests: We prove that there is no universal $\Pi^0_1$-independence test in case both measures are $m$ (Theorem 7.3).

the referee we use the more liberal definition. For the questions studied in this paper the difference is immaterial, and the presentation of Sect. 7 becomes much smoother with this definition.
We end this section with some notation and terminology. As we already said, $\omega$ is the set of natural numbers. This set is effectively bijective with the set of all finite binary strings.

A function $f$ is $\Sigma^0_1$, or computably enumerable, if it is computably approximable from below, that is, if there exists a computable function $\hat{f}(x, s)$ that is monotonic nondecreasing in $s$ such that $\lim_{s} \hat{f}(x, s) = f(x)$. Similarly, $f$ is $\Pi^0_1$ if it is computably approximable from above, i.e. the approximation $\hat{f}$ is monotonic nonincreasing in $s$.

A function $P : \omega \to \mathbb{R}$ is a probability measure if $\sum_x P(x) = 1$. Since every $\Sigma^0_1$-measure is computable (Proposition 3.1), in computability theory it is often natural to consider semimeasures. A function $P : \omega \to \mathbb{R}$ is a semimeasure if $\sum_x P(x) \leq 1$.

A function $f$ dominates a function $g$ if $f(x) \geq g(x)$ for almost every $x$, and $f$ additively dominates $g$ there is a constant $c$ such that $f(x) + c \geq g(x)$ for every $x$. As in [10], we call a function $f$ universal or additively optimal for a class $C$ if $f \in C$ and $f$ additively dominates all other functions in $C$. A function is called an order if it is monotone and unbounded. Given two functions $d$ and $d'$, the phrase “$d' - d$ is unbounded” abbreviates the statement that for all $i$ there is $x$ such that $d'(x) - d(x) \geq i$.

2 Some General Notes on $\Sigma^0_1$- and $\Pi^0_1$-Functions

As a preparation for sections to follow, we list some basic folk facts about $\Sigma^0_1$- and $\Pi^0_1$-functions.

(i) There is no universal $\Sigma^0_1$-function. Namely if $f \in \Sigma^0_1$ then also the function $\lambda x. f(x) + x$ is $\Sigma^0_1$.

(ii) The reason we cannot build a universal (additively optimal) $\Sigma^0_1$-function is that the $\Sigma^0_1$-functions are not uniformly enumerable; in an effective enumeration of the computable approximations (which does exist) we cannot effectively separate those that remain finite from the ones that grow unbounded. That there is a universal Martin-Löf test (Martin-Löf) and that there is a universal $\Sigma^0_1$-semimeasure (Levin, Theorem 3.2) holds because these $\Sigma^0_1$-objects satisfy an extra boundedness condition that we can check along the way to see if it is violated, and if so render the object harmless by discarding it after finitely many steps.

(iii) The $\Pi^0_1$-functions are also not uniformly enumerable, but for a different reason: Every $\Pi^0_1$-function is computably bounded (namely by any of its computable approximations). If there were a universal $\Pi^0_1$-function, its computable bound would in particular dominate all computable functions, which is impossible.

2Note that the term universal is used here to refer to growth rates, and should not be confused with the other common usage of the term, referring to the ability to enumerate all other functions in the class.

3This translation of Schnorr’s term “Ordnungsfunktion” [15] has meanwhile become standard in randomness theory.
(iv) Not every $\Sigma^0_1$-function is computably bounded: Take an effective enumeration of all partial computable functions $\varphi_e$ and define
\[ f(x) = \sum \{ \varphi_i(i) : i \leq x \land \varphi_i(i) \downarrow \}. \]
This $f$ is a $\Sigma^0_1$-order dominating any computable function.

(v) Given any order $f$ we can define a slow growing inverse $h$ of $f$ by
\[ h(x) = \mu n. f(n) \geq x. \]
If $f \in \Sigma^0_1$ then $h \in \Pi^0_1$, so if we take for $f$ the fast growing function from the previous item then we obtain an $\Pi^0_1$-order dominated by any computable order.

(vi) Conversely, given a fast growing $\Sigma^0_1$-order $f$ we can define a slow growing $\Pi^0_1$-order $h$ by
\[ f(x) = \mu n. h(n) \geq x. \]
Hence, since there are no universally fast growing $\Sigma^0_1$-orders, we see that there are no universally slow growing $\Pi^0_1$-orders.

(vii) Any $\Sigma^0_1$-order dominates a computable order: Given a $\Sigma^0_1$-order one easily constructs a slower growing computable order. This is also true for nonmonotonic functions: For any unbounded $\Sigma^0_1$-function $f$ one can find an unbounded computable $g$ such that the function $f - g$ is positive and unbounded.

In conclusion: $\Sigma^0_1$-orders can grow faster but not slower than any computable one, whereas $\Pi^0_1$-orders can grow slower but not faster than any computable one.

3 General Notes on Measures and Semimeasures

For the record we state the following

**Proposition 3.1**

1. Every $\Sigma^0_1$-measure is computable,
2. There is a $\Pi^0_1$-measure that is not computable.

**Proof** 1. This well-known and easy to see: If $P \in \Sigma^0_1$ with computable approximation $P_s$ and $\sum_x P(x) = 1$ then to approximate $P(x)$ to within $\varepsilon$, find a stage $s$ such that $1 - \sum_x P_s(x) < \varepsilon$. Then $P(x) - P_s(x) < \varepsilon$.

2. Let $X$ be any noncomputable $\Pi^0_1$-set, with computable approximation $X_s$. Define a measure $P$ as follows: At stage $s$ assign the $s$ values $2^{-1}, \ldots, 2^{-s}$ to the first $s$ elements of $X_s \subseteq X_{s-1}$, in such a way that the elements of $X_s$ that were already assigned a value at a previous stage retain this, and the values that were assigned to elements in $X_{s-1} - X_s$ are given a new host element. For any element $x \notin X$ we define $P(x) = 0$. Then $P \in \Pi^0_1$, and $P$ is not computable because otherwise, since $x \in X \iff P(x) > 0$, $X$ would also be computable. Note that in general $P(x) > 0$ is not decidable for computable $P$, but in this case it is: $x$ is assigned an initial value
$2^{-i}$ with $i \leq x$. Computing $P(x)$ to within precision $2^{-i-1}$ decides whether it is $2^{-i}$ or 0. □

A semimeasure $P$ (multiplicatively) dominates a semimeasure $Q$ if there is a rational constant $q > 0$ such that $P(x) > qQ(x)$. A semimeasure $P$ is (multiplicatively) universal for a class of semimeasures $C$ if $P \in C$ and $P$ dominates every $Q \in C$. As quoted above, Levin showed that there is a universal $\Sigma^0_1$-semimeasure. Not surprisingly, there is no $\Pi^0_1$ one.

**Theorem 3.2** (Levin) There exists a universal $\Sigma^0_1$-semimeasure $m$.

**Proof** We sketch the proof for later reference. Let $P_i$ be an effective enumeration of all $\Sigma^0_1$-semimeasures. Note that such an enumeration can be obtained because we can see in finitely many steps whether the condition $\sum_x P_i(x) \leq 1$ is violated. Define

$$m(x) = \sum_i 2^{-i} P_i(x).$$

Clearly $m(x)$ is finite, $m \in \Sigma^0_1$, and $m$ is multiplicatively universal. □

The following easy facts are also well-known in the folklore of the field:

**Proposition 3.3**

(i) There is no universal computable semimeasure.

(ii) There is no universal $\Pi^0_1$-semimeasure.

**Proof** Both item (i) and (ii) follow from the following. Let $P$ be a $\Pi^0_1$-semimeasure. We construct a computable semimeasure $Q$ such that

$$\forall q \in \mathbb{Q}^>0 \exists x \quad P(x) < qQ(x). \quad (3)$$

Given $q$ we simply search for an $x$ where $P(x)$ is small and set a large value for $Q(x)$. Note that $x$ can be found effectively since $P \in \Pi^0_1$. More precisely, given $q = 2^{-i}$ find a fresh $x$ such that $P(x) < 2^{-2i}$. Set $Q(x) = 2^{-i}$, and to make $Q$ total set $Q(y) = 0$ for all $y < x$ that were not yet defined. The $Q$ thus constructed is computable, clearly satisfies (3), and $\sum_x Q(x) = \sum_i 2^{-i} = 1$. □

**Corollary 3.4** Let $m$ be the universal $\Sigma^0_1$-semimeasure and let $P$ be a $\Pi^0_1$-semimeasure. Then the function $m(x)/P(x)$ is unbounded. In particular, $m(x) > P(x)$ infinitely often.

**Proof** Suppose for a contradiction that $c \in \omega$ is a constant such that $m(x)/P(x) \leq c$ for every $x$. By Proposition 3.3, let $Q$ be a computable measure such that (3) holds. Then a fortiori

$$\forall q \in \mathbb{Q}^>0 \exists x \quad m(x) < q \cdot c \cdot Q(x),$$

contradicting that $m$ is multiplicatively universal. □
Call a semimeasure \( P \) monotone if \( x \leq y \) implies \( P(x) \geq P(y) \). We note that there does not exist a monotone universal \( \Sigma^0_1 \)-semimeasure. This is not difficult to prove directly, but it also follows from the Coding Theorem (10) below. Namely, if \( m \) is universal then \( -\log m(x) = K(x) \) up to a fixed additive constant, hence if \( m \) were monotone then \( K \) would also be monotone, which is of course not the case. There is a \( \Sigma^0_1 \)-semimeasure that is multiplicatively universal among the monotonic ones, namely \( m'(x) = \min_{y \leq x} m(y) \), which is within a multiplicative constant equal to \( \frac{1}{xm(\log x)} \).

4 \( \Sigma^0_1 \)-Sum-Tests

In Li and Vitányi [10, Theorem 4.3.5] it is proven that for every strictly positive computable measure \( P \) the \( \Sigma^0_1 \)-function

\[
\log \left( \frac{m(x)}{P(x)} \right)
\]

is a \( \Sigma^0_1 \)-universal sum-test for \( P \). In particular, since by Corollary 3.4 the function \( m(x)/P(x) \) is unbounded, there is an unbounded \( P \)-sum-test. We prove here that for \( P = m \) this is no longer true.

**Proposition 4.1** For any unbounded \( \Sigma^0_1 \) function \( d : \omega \to \mathbb{Z} \) there is a computable measure \( P \) such that

\[
\sum_{x \in \omega} P(x)2^{d(x)} = \infty. \tag{4}
\]

**Proof** Suppose that \( d : \omega \to \mathbb{Z} \) is \( \Sigma^0_1 \) and unbounded. We construct a computable measure \( P \) such that

\[
\sum_{x \in \omega} P(x) = 1 \tag{5}
\]

and (4) holds. The construction is in \( \omega \) stages. At stage \( s \), search for a fresh (i.e. hitherto not used in the construction) element \( x \) such that \( d(x) \geq s \). Such \( x \) can be found effectively since \( d \) is unbounded and \( \Sigma^0_1 \). For this \( x \) define \( P(x) = 2^{-s} \). To make sure that \( P \) is total, define \( P(y) = 0 \) for all \( y < x \) for which \( P(y) \) was not yet defined at a previous stage. End of construction.

Clearly the \( P \) thus constructed satisfies (4) and (5), since at stage \( s \) of the construction we contribute an amount of \( 2^{-s} \) to \( \sum_x P(x) \) and an amount of at least 1 to \( \sum_x P(x)2^{d(x)} \).

**Corollary 4.2** Every \( \Sigma^0_1 \)-sum-test for the universal \( \Sigma^0_1 \)-semimeasure \( m \) is bounded.

**Proof** Suppose that \( d \) is unbounded. Let \( P \) be as in Proposition 4.1. Since \( m \) is universal, there is \( q > 0 \) with \( m(x) \geq qP(x) \) for all \( x \). Then \( \sum_x m(x)2^{d(x)} \geq \sum_x qP(x)2^{d(x)} = \infty \), hence \( d \) is not a sum-test for \( m \). \( \square \)
We remark that for every computable semimeasure $P$ there is a computable order $d$ that is a sum-test for $P$, as is easily seen. (One can use for example the proof of Proposition 6.1 below, taking $d$ constant.)

For later purposes we note the following variant of Proposition 4.1:

**Proposition 4.3** If $d$ and $d'$ are computable functions such that the function $d' - \max(0, d)$ is unbounded, then there is a computable semimeasure $P$ such that

$$\sum_{x \in \omega} P(x)2^{d'(x)} = \infty$$  \hspace{1cm} (6)

and

$$\sum_{x \in \omega} P(x)2^{d(x)} \leq 1.$$  \hspace{1cm} (7)

That is, $d$ is a sum-test for $P$ and $d'$ is not.

**Proof** The proof is similar to that of Proposition 4.1, except that at stage $s$ we now search for a fresh number $x$ such that

$$d'(x) - \max(0, d(x)) \geq s.$$  

For this $x$ define $P(x) = 2^{-\max(0, d(x)) - s}$. Again, to make $P$ total, define $P(y) = 0$ for all $y < x$ for which $P(y)$ was not yet defined at a previous stage. Note that $P$ is indeed a semimeasure.

Now $P$ satisfies (6) and (7), since at stage $s$ of the construction we contribute an amount of $2^{-\max(0, d(x)) - s}2^{d(x)} \leq 2^{-s}$ to $\sum_x P(x)2^{d(x)}$ and an amount of $P(x)2^{d'(x)} \geq 2^{-\max(0, d(x)) - s}2^{\max(0, d(x)) + s} = 1$ to $\sum_x P(x)2^{d'(x)}$.  \hspace{1cm} \Box

Finally, we claim that there is a semimeasure $P \in \Sigma^0_1$ without $\Sigma^0_1$-universal sum-test. This is trivial to see if we allow $P(x) = 0$ for infinitely many $x$, but it also holds for strictly positive $P$:

**Proposition 4.4** There exists a strictly positive $\Sigma^0_1$-semimeasure $P$ such that there is no $\Sigma^0_1$-universal sum-test for $P$.

**Proof** Since the constant zero function is a sum-test for any semimeasure, a universal sum-test is bounded from below by some constant $k \in \mathbb{Z}$. So in proving that such a universal sum-test does not exist we may restrict ourselves to such functions.

Let $d_i$ be an effective enumeration of all $\Sigma^0_1$-functions from $\omega$ to $\mathbb{Z} \cup \{ \infty \}$ that are bounded from below by some (possibly negative) constant. (The latter assumption is needed to have an effectively enumerable class of functions; for the rest of the proof it is not needed.) Let $d_{i,s}$ denote the approximation of $d_i$. We construct a semimeasure $P \in \Sigma^0_1$ and functions $d'_i \in \Sigma^0_1$ so that for every $i$ it holds that $d'_i - d_i$ is unbounded and

$$\sum_x P(x)2^{d'_i(x)} \leq 1 \implies \sum_x P(x)2^{d_i(x)} \leq 1.$$  \hspace{1cm} (8)
Let \((x, y)\) be a bijective pairing function from \(\omega^2\) to \(\omega\). We assign an infinite computable domain \(R_i\) to the strategy for \(d_i\) as follows. Define

\[ R_i = \{ (x, i) : x \in \omega \} \]

and

\[ d'_{i,s}(x) = \begin{cases} d_{i,s}(x) + x & \text{if } x \in R_i \\ 0 & \text{otherwise.} \end{cases} \]

We construct \(P\) by defining its approximation \(P_s\) as follows. Let \(P_0(x) = 2^{-2x-1}\), so that \(P\) is strictly positive. At stage \(s\) of the construction, for every \(i \leq s\), if \(s\) is the first stage such that

\[ \sum_{x < s} P(x) 2^{d'_{i,s}(x)} > 1 \tag{9} \]

then define

\[ P_{s+1}(x) = P_s(x) 2^{d'_{i,s}(x)-d_{i,s}(x)} = P_s(x) 2^x \]

giving every \(x \in R_i\). Note that since this can happen only once, we have that \(P_s(x)\) equals either \(P_0(x)\) or \(P_0(x) 2^x\). This ends the construction.

We check that requirements (8) are satisfied for every \(i\). Suppose that \(\sum_x P(x) 2^{d'_i(x)} > 1\). Then (9) holds for some \(s\), hence

\[ \sum_{x \in \omega} P(x) 2^{d_i(x)} \geq \sum_{x \notin R_i} P_s(x) 2^{d'_{i,s}(x)} + \sum_{x \in R_i} P_{s+1}(x) 2^{d'_{i,s}(x)} \]

\[ \geq \sum_{x \notin R_i} P_s(x) + \sum_{x \in R_i} P_{s+1}(x) 2^{d'_{i,s}(x)-d_{i,s}(x)} 2^{d_{i,s}(x)} \]

\[ \geq \sum_{x \notin R_i} P_s(x) + \sum_{x \in R_i} P_s(x) 2^{d'_{i,s}(x)} \]

\[ = \sum_{x \in \omega} P_s(x) 2^{d'_{i,s}(x)} > 1 \]

hence (8) is satisfied. Clearly \(P \in \Sigma_1^0\), so it only remains to show that \(P\) is a semi-measure. Since the domains \(R_i\) partition \(\omega\) we have

\[ \sum_{x \in \omega} P(x) = \sum_i \sum_{x \in R_i} P(x) \]

\[ \leq \sum_i \sum_{x \in R_i} P_0(x) 2^x \]

\[ = \sum_i \sum_{x \in R_i} 2^{-x-1} \]

\[ = \sum_{x \in \omega} 2^{-x-1} = 1. \]
5 Unbounded $\Pi_1^0$-Sum-Tests

We saw in Sect. 4 that there are $\Sigma_1^0$-semimeasures with no nontrivial sum-tests: all $\Sigma_1^0$-sum-tests for $m$ are bounded. We now prove that for $\Pi_1^0$ there are nontrivial, unbounded, examples.

**Proposition 5.1** For every $\Sigma_1^0$-semimeasure $P$ there is a $\Pi_1^0$-order $d$ that is a sum-test for $P$.

**Proof** The idea is to monitor the tails of the sum $\sum_x P(x)$, and estimate at every stage the first element $x_i$ such that $\sum_{y \geq x_i} P(y) \leq 2^{-i}$. The $x_i$ may grow, but eventually come to a finite limit. If we know them we can add suitable large factors $2^{d(x)}$ that satisfy $\sum_x P(x)2^{d(x)} \leq 1$. If $x_i$ turned out to be wrong, we simply decrease $d(x)$, but we have to do this only finitely often. Formally the construction proceeds as follows.

Start with $x_{i,0} = i$. At stage $s$, when 

$$ \sum_{y \geq x_{i,s}} P_s(y) \leq 2^{-i} $$

let $x_{i,s+1} = x_{i,s}$, otherwise set $x_{j,s+1} = x_{j,s} + 1$ for all $j \geq i$. For all $x \in [x_{i,s}, x_{i+1,s})$ define

$$ d_s(x) = \lfloor \log i \rfloor. $$

End of construction.

First note that $\lim_s x_{i,s} = x_i$ exists for every $i$ since $\sum_s P(x)$ converges. Since $x_{i,s}$ is nondecreasing, $d_s(x)$ can only decrease, and since the limit exists it can do so only finitely many times. Hence $d \in \Pi_1^0$, and it is unbounded since $d(x_i) = \lfloor \log i \rfloor$. Finally, 

$$ \sum_{x \in \omega} P(x)2^{d(x)} \leq \sum_{i \in \omega} \sum_{x \in [x_i, x_{i+1})} P(x)2^{\log i} $$

$$ \leq \sum_{i \in \omega} i \sum_{x \geq x_i} P(x) $$

$$ \leq \sum_{i \in \omega} 2^{-i}i = 2. $$

Therefore, $d(x) - 1$ defines a sumtest for $P$.  \hfill $\square$

We can improve Proposition 5.1 as follows:

---

4Note that since $d_0(x) = \log x$, $d_s(x)$ can change at most $\log x$ times, but the number of times $x_{i,s}$ changes is not computably bounded. Hence the limit function $d$ can in general be very slow growing, that is, be dominated by any computable order.
Proposition 5.2 For every $\Sigma^0_1$-semimeasure $P$ and every computable sum-test $d$ for $P$, there is a $\Pi^0_1$-sum-test $d'$ for $P$ such that $d' - d$ is unbounded. If $d$ is an order then $d'$ can be chosen to be an order as well.

Proof The proof is similar to that of Proposition 5.1. The only difference is that we now monitor the tails of the sum $\sum_x P(x)2^{d(x)}$, and estimate at every stage the first element $x_i$ such that $\sum_{y \geq x_i} P(y)2^{d(y)} \leq 2^{-i}$. If this holds at stage $s$, we let $d'_s(x) = d_s(x) + \lfloor \log i \rfloor$ for all $x \in [x_{i,s}, x_{i+1,s})$. That $\lim_{s \to \infty} x_{i,s}$ exists follows because $d$ is computable, so the values $P_s(x)2^{d_s(x)}$ can only go up. If $d$ is an order then $d'$ is also an order. □

We now turn to the rate of growth of sum tests. If $d$ is any (not necessarily $\Pi^0_1$) $m$-sum-test then $d$ does not grow very fast:

Proposition 5.3 If $d$ is any $m$-sum-test then $d$ is dominated by all $\Pi^0_1$-functions $f$ with

$$\sum_{x \in \omega} 2^{-f(x)} < \infty.$$ This also holds on any computable subset $R \subseteq \omega$: $d(x) \leq f(x)$ for almost every $x \in R$ whenever $\sum_{x \in R} 2^{-f(x)} < \infty$.

Proof We prove only the first part, since the second is just an easy modification. Given $f$ as above, suppose that $f$ does not dominate $d$, so that $d(x) > f(x)$ infinitely often. We produce a semimeasure $P \in \Sigma^0_1$ such that $d$ is not a sum-test for $P$. (Hence by universality of $m$ the same holds with $m$ in place of $P$.) Simply put $P(x) = 2^{-f(x)}$ for every $x$. Then $\sum_x P(x) < \infty$, so a suitable tail of $P$ is a semimeasure. Without loss of generality we may assume that $P$ itself is a semimeasure. Since $f \in \Pi^0_1$ we have $P \in \Sigma^0_1$. Finally,

$$\sum_{x \in \omega} P(x)2^{d(x)} \geq \sum_{d(x) \geq f(x)} P(x)2^{d(x)} \geq \sum_{d(x) \geq f(x)} 2^{-f(x)}2^{f(x)} = \infty,$$

hence $d$ is not a $P$-sum-test. □

Corollary 5.4 If $d$ is a $\Pi^0_1$-sum-test for $m$ then $\sum_x 2^{-d(x)} = \infty$.

Proof If we would have $\sum_x 2^{-d(x)} < \infty$ then also $\sum_x 2^{-(d(x)-1)} < \infty$, hence by Proposition 5.3 the $\Pi^0_1$-function $d(x) - 1$ would dominate $d$, contradiction. □

Next we turn to the question when a sum-test can be replaced by an order dominating it.

Proposition 5.5 There exist a computable measure $P$ and a computable $P$-sum-test $d$ such that every (not necessarily effective) order $d'$ dominating $d$ is not a $P$-sum-test.
Proof To construct $P$ and $d$, simply let $d(x)$ be large when $P(x)$ is small and vice versa: For every $x$ define

$$
P(2x) = 0, \quad d(2x) = x,
$$

$$
P(2x + 1) = 2^{-x-1}, \quad d(2x + 1) = 0.
$$

Clearly $P$ is a measure and $d$ is a $P$-sum-test. If $d'$ is an order dominating $d$ then $d'(2x + 1) \geq d'(2x) \geq d(2x) = x$, hence $\sum_x P(x)2^{d'(x)} \geq \sum_x 2^{-x-1}2^x = \infty$.

Proposition 5.5 also holds if we require that $P$ be strictly positive, with the same proof idea. At this point we ask what happens when $P = m$ and $d \in \Pi_1^0$:

**Question 5.6** Suppose that $d$ is a $\Pi_1^0$-sum-test for $m$. Is there always a $\Pi_1^0$-order $d'$ dominating $d$ that is a sum-test for $m$?

6 Universal $\Pi_1^0$-Sum-Tests

We have seen that for the universal $\Sigma_1^0$-semimeasure $m$ there are only trivial $\Sigma_1^0$-sum-tests, namely the bounded ones, and that there are nontrivial $\Pi_1^0$-sum-tests for $m$. In this section we investigate if $\Sigma_1^0$-semimeasures can have a universal $\Pi_1^0$-sum-test. We do not obtain a complete answer to this question, but only prove that no universal $\Pi_1^0$-sum-test exists in specific cases. In particular we leave open the case of universal $\Sigma_1^0$-semimeasures.

**Proposition 6.1** Suppose that $P$ is a computable semimeasure. Then there is no universal $\Pi_1^0$-sum-test for $P$.

Proof The idea is similar to that of Proposition 3.3. Given $d \in \Pi_1^0$ such that $\sum_x P(x)2^{d(x)} \leq 1$, construct $d' \in \Pi_1^0$ such that for all $i$ there is $x$ such that $d'(x) \geq d(x) + i$. Given $i$, effectively search for $x$ such that $P(x)2^{d(x)} < 2^{-2i}$ (which is possible since such $x$ exist and $d \in \Pi_1^0$), so that $P(x)2^{d(x)+i} < 2^{-i}$. For this $x$ define $d'(x) = d(x) + i$, and set $d'(y) = d(y)$ for all $y < x$ for which $d'(y)$ was not yet defined. Then

$$
\sum_{x \in \omega} P(x)2^{d'(x)} \leq \sum_{d'(x)=d(x)} P(x)2^{d(x)} + \sum_{i \in \omega} 2^{-i} < \infty,
$$

hence $d' - c$, for some $c$ large enough, is a $\Pi_1^0$-sum-test for $P$ not dominated by $d$. □

Note that the proof of Proposition 6.1 in fact works for every $\Pi_1^0$-semimeasure $P$.

**Proposition 6.2** If a $\Sigma_1^0$-semimeasure $P$ has a coinfinite support, i.e. if $P(x) = 0$ for infinitely many $x$, then there is no universal $\Pi_1^0$-sum-test for $P$.  

\( \copyright \) Springer
**Proof** Given a $\Pi_1^0$-sum-test $d$ and a computable order $f$, define the function 

$$d'(x) = \begin{cases} 
  d_t(x) + f(x) & \text{if } P_t(x) = 0 \\
  d_t(x) & \text{otherwise}.
\end{cases}$$

Remark that $d' = \lim d'_t$ is again a $\Pi_1^0$-sum-test for $P$. If $P$ has a coinfinite support then $d'(x) - d(x)$ is unbounded, hence $d$ is not $\Pi_1^0$-universal. \hfill \square

**Corollary 6.3** If $P \in \Sigma_1^0$ does not have a strictly positive computable lower bound (i.e. a computable $Q$ such that $P(x) \geq Q(x) > 0$ a.e. $x$) then there is no universal $\Pi_1^0$-sum-test for $P$.

**Proof** This follows from Proposition 6.2, since if $P \in \Sigma_1^0$ is a.e. strictly positive then it has such a computable lower bound. \hfill \square

**Question 6.4** Let $P$ be any $\Sigma_1^0$-semimeasure. Then there is no universal $\Pi_1^0$-sum-test for $P$. In particular there is no universal $\Pi_1^0$-sum-test for $m$.\(^5\)

In the remaining part of this section we make some further remarks about universal sum-tests. We first prove that there are $\Sigma_1^0$-semimeasures $P$ for which the class of computable sum-tests has a universal element. In fact, every computable function is such a universal sum-test:

**Proposition 6.5** Given any computable function $d : \omega \to \omega$, the $\Sigma_1^0$-semimeasure 

$$P(x) = m(x)2^{-d(x)}$$

satisfies:

- $d$ is (additively) universal for the class 

  $$\{ d' \text{ computable : } d' \text{ is } P\text{-sum-test} \},$$

- $P$ is (multiplicatively) universal for the class 

  $$\{ P' \in \Sigma_1^0 : d \text{ is } P'\text{-sum-test} \}.$$

**Proof** For the first item, suppose that $d'$ is a sum-test for $P$ that is not additively dominated by $d$, i.e. $d' - d$ is unbounded. Then $P'(x) = m(x)2^{d'(x)-d(x)}$ is a $\Sigma_1^0$-semimeasure that is not multiplicatively dominated by $m$, contradicting Theorem 3.2. For the second item, suppose that $P'$ is a $\Sigma_1^0$-semimeasure for which $d$ is a sum-test. Then $Q(x) = P'(x)2^{d(x)}$ is a $\Sigma_1^0$-semimeasure, hence by Theorem 3.2, $P(x)2^{d(x)} = \ldots$

\(^5\)Note added in proof: There is now a draft by the first author containing a concept proof solving the second part of this question for $m$ in the affirmative.
Note that the proof of Proposition 6.5 does not work for $\Pi_1^0$-functions: For $d$ constant we obtain the universal semimeasure $m$, but by Proposition 5.1 there are $\Pi_1^0$-functions $d'$ dominating every constant that are still sum-tests for $m$, hence $d'$ is not universal. In fact, Proposition 5.2 shows that Proposition 6.5 fails for $\Pi_1^0$: There are $d \not\in \Pi_1^0$ that are not $\Pi_1^0$-universal for any $P \in \Sigma_1^0$, namely any computable $d$. In Proposition 6.6 we show that, given a computable $d$, there is even a uniform witness $d'$ showing that $d$ is not $\Pi_1^0$-universal.

Say that a given semimeasure $P$ splits two functions $d$ and $d'$ if $d$ is a $P$-sum-test and $\sum_x P(x)2^{d'(x)} = \infty$ (in that order). Proposition 4.3 says that every pair of computable $d$ and $d'$ with $d' - d$ unbounded can be split by a computable semimeasure.

**Proposition 6.6** For any computable $d : \omega \to \omega$, there is $d' \in \Pi_1^0$ such that $d' - d$ is unbounded and such that no $\Sigma_1^0$-semimeasure splits $d$ and $d'$.

**Proof** Let $P(x) = m(x)2^{-d(x)}$ be as in Proposition 6.5. Let $d'(x) = d(x) + b(x)$ where $b$ is the unbounded sum-test for $m$ as constructed in Proposition 5.1. Suppose that $Q$ is a $\Sigma_1^0$-semimeasure and that $d$ is a sum-test for $Q$. Then $P$ dominates $Q$ by Proposition 6.5. If $q > 0$ is such that $qQ(x) < P(x)$ then

$$\sum_x Q(x)2^{d'(x)} \leq \frac{1}{q} \sum_x P(x)2^{d'(x)}$$

$$= \frac{1}{q} \sum_x m(x)2^{-d(x)}2^{d(x) + b(x)}$$

$$\leq \frac{1}{q} < \infty.$$ 

Hence $Q$ does not split $d$ and $d'$.

### 7 Independence Tests

Recall the definition of independence test from Sect. 1. The results about sum-tests from previous sections also hold, mutatis mutandis, for the binary case of independence tests, with the same proofs except for Proposition 6.5. In particular, in the case of $P = Q = m$, Corollary 4.2 now states that there are no unbounded computable and $\Sigma_1^0$-independence tests. There exist unbounded $\Pi_1^0$ tests and we will show that there is no $\Pi_1^0$-universal test (Theorem 7.3). Note that this answers the binary analogue of Question 6.4. As a corollary to the proof it follows that for all enumerable semimeasures $P$, $Q$, a $\Pi_1^0$-independence test for $(P, Q)$ exist, with $d(x, y) \geq l(x) - O(\log l(x))$ for infinitely many binary strings $x, y$ with length $l(x) = l(y)$, and for each $\Pi_1^0$-independence test $d$ for $(m, m)$, there is a test $d'$ such that $d'(x, y) - d(x, y)$ exceeds $l(x) - O(\log l(x))$ infinitely often. Since $P = Q = m$
throughout this section, “independence test” will abbreviate “independence test for \( m \) and \( m \).

We start with an informal argument why there is no \( \Pi^0_1 \)-universal independence test. Consider the set
\[
D = \{(x, y) : l(x) = l(y) \land x, y \text{ random and dependent}\}.
\]

\( D \) is a natural example of a d.c.e. set, that is, a set that is the difference of two c.e. sets, in this case the set of pairs \((x, y)\) with \( x \) and \( y \) dependent minus the set of pairs where one of \( x \) and \( y \) is not random. Now suppose that \( d \) is a \( \Pi^0_1 \) independence test. As pointed out in Sect. 1, it follows directly from (2) that the set of pairs \((x, y)\) where \( d(x, y) \) is large, is small in measure. Thus \( d \) provides us with an effective method for detecting dependencies in such pairs. Now suppose that for all \((x, y)\) \( \in D \), \( d(x, y) \) would be large. Then we would have that \( x \) and \( y \) are dependent if and only if \( d(x, y) \) is large. Since the latter is a \( \Pi^0_1 \)-event, we obtain that \( D \in \Pi^0_1 \), a contradiction.

This means that there are \((x, y) \in D\) such that \( d(x, y) \) is small, that is, \( x \) and \( y \) are dependent but \( d \) does not see this. Since \( D \) is a set of small measure, we could construct a new \( d' \) with \( d' \) higher on such pairs (thus showing that \( d \) is not universal).

To recognize such pairs, we have to recognize more dependencies than \( d \) does by allowing for more computation time. Some pairs \((x, y)\) may fall through at a later time when it turns out that one of \( x \) and \( y \) is not random, but if we allow for enough computation time we will also find pairs in \( D \) that were not recognized by \( d \), and hence we can show that \( d \) is not universal. The proof below is more informative, since it shows that the functions \( d^i \) of the specific form defined there form a strict hierarchy of independence tests, and that every independence test is dominated by some \( d^i \).

In this section we use Kolmogorov complexity. For general background we refer to Li and Vitányi [10] and the forthcoming Downey and Hirschfeldt [4]. We fix our notation for this section. Let \((x, y)\) denote a computable bijective mapping from \( \omega \times \omega \) to \( \omega \). Let \( \Phi \) be an optimal universal prefix-free Turing machine. \( \Phi_s(p | z) \downarrow = x \) if and only if \( \Phi(p | z) \) outputs \( x \) in less than \( s \) steps using an auxiliary tape for string \( z \). The prefix-free complexity functions are \( K_s(x | z) = \min\{l(p) : \Phi_s(p | z) \downarrow = x\} \), \( K(x | z) = \lim_s K_s(x | z) \), \( K(x) = K(x | \emptyset) \), and \( K(x, y) = K((x, y)) \). The complexity of a partial computable function \( f \) is defined by
\[
K(f) = \min\{l(p) : \forall x \in \text{dom} f [\Phi(p | x) \downarrow = f(x)]\}.
\]

The algorithmic complexity of a one-argument \( \Sigma^0_1 \)-function or \( \Pi^0_1 \)-function \( d(x) \) is given by the lowest complexity \( K(d_t(x)) \) of a two-argument function \( d_t(x) \) that is the computable approximation of \( d(x) \) as \( t \to \infty \). \( f(x) \leq^+ g(x) \) or \( f(x) \leq g(x) + O(1) \) means that there exists a constant \( c \) such that for all \( x \) as indicated or allowed in the context of the proof, we have: \( f(x) \leq g(x) + c \). \( f(x) =^+ g(x) \) means \( f(x) \leq^+ g(x) \) and \( g(x) \leq^+ f(x) \). Similarly for the \( O(\log) \) notation. Theorem 3.2 stated the existence of a universal \( \Sigma^0_1 \)-semimeasure. The Coding Theorem [10] states that the function
\[
m(x) = 2^{-K(x)}
\]
is a multiplicatively universal $\Sigma^0_1$-semimeasure. Let $l(x)$ be the length of the number $x$, seen as a finite binary string, and let from now on $n$ be short for $l(x)$.

**Definition 7.1**

- $R = \{(x, y) : l(x) = l(y) \land K(x), K(y) \geq n - \log n\}$.
- A function $f$ $R$-dominates $g$ (notation $f \succeq_R g$) if
  \[ \exists c \forall \infty (x, y) \in R[f(x, y) + c \log n \geq g(x, y)]. \]
- Define for each $i$ the total functions:
  \[ T^i(n) = \max\{\Phi(p|m) : l(p) \leq i, \lambda m.\Phi(p|m) \text{ is total}\}, \]
  \[ K^i(x, y) = K_{T^i(l((x, y)))}(x, y), \]
  \[ K^i(x) = K^i(x, \emptyset), \]
  \[ d^i(x, y) = K(x) + K(y) - K^i(x, y). \]

Note that domination implies $R$-domination and that $R$-domination defines a semi-order on the binary functions. The function $T^i(n)$ is $\emptyset''$-computable, but for fixed $i$ it is computable. Hence for fixed $i$ also $K^i(x, y)$ is computable.

There is a prefix-free code such that every $n \in \omega$ is encoded with length $2 \log n$. Let $z$ be the binary expansion of $n$. Remark that $l(z) = \lceil \log n \rceil$. The code word $z_00z_10z_20\ldots z_{\lceil \log n \rceil}1$ for $n$ has length $2 \log n$. Remark that the set of these code words is prefix-free. The time needed to decode this sequence is bounded by a computable function of $n$. Combining a prefix-free code for $n$ with a prefix-free code for $x$ given $n$ results in a prefix-free code for $x$. Therefore, without loss of generality it can be assumed about the universal machine $\Phi_1$ implicit in $K$ that:

\[ \exists c \forall i \exists x[K^{i+c}(x) - 2\log n - c \leq K^i(x|n) \leq K^i(x)]. \] (11)

**Lemma 7.2** For all $i$, $d^i$ is a $\Pi^0_1$-independence test.

**Proof** Since $K$ is a $\Pi^0_1$-function, $d^i$ is $\Pi^0_1$. Clearly $d^i(x, y)$ is increasing in $i$ and $\lim_i K^i(x, y) = K(x, y)$, therefore:

\[ d^i(x, y) \leq K(x) + K(y) - K(x, y), \]

and

\[ \sum_{x, y} m(x)m(y)2^{d^i(x, y)} \leq \sum_{x, y} 2^{-K(x, y)} \leq 1. \]

**Theorem 7.3** There is no universal $\Pi^0_1$-independence test.
Proof Because domination implies R-domination, the absence of a universal element in the set of $\Pi_1^0$ independence tests follows from the absence of a universal element with respect to $R$-domination: if there were a $\Pi_1^0$-independence test dominating all other $\Pi_1^0$-independence tests, it would also R-dominate any $\Pi_1^0$-independence test. We show in two steps that this is impossible

- **Lemma 7.5** For all $\Pi_1^0$-independence tests $d$, there is an $i$ such that $d^i \succ d$.

- **Lemma 7.9** For all $i$, there is a $j$ such that $d^i \not\succ d^j$.

Suppose $d$ were R-universal, then by Lemma 7.5 and by transitivity of R-domination, there should also be an R-universal element among the set of $d^i, i \in \omega$. However this is not possible by Lemma 7.9.

In the proof of Lemma 7.5 and 7.6 the following lemma is used.

**Lemma 7.4** For all $n$, let $P(x, y|n) > 0$ be a positive computable semimeasure over all binary strings $x, y$, with $l(x) = l(y) = n$. If for some $i$, there is a binary string $p$ satisfying:

$$\Phi_{T^i(n)}(p|x, y, n) \downarrow = \lceil -\log P(x, y|n) \rceil,$$

then

$$K^{i+O(1)}(x, y|n) \leq l(p) - \log P(x, y|n).$$

**Proof** For any computable semimeasure $P$, Shannon-Fano coding [10] provides a prefix-free code for all $(x, y)$ of length $n$ with maximal encoding length $-\log P(x, y|n) + O(1)$. To decode the Shannon-Fano code of $(x, y)$, a fixed algorithm needs to be executed that requires an amount of computation steps bounded by $f(n, T^i(n)) \leq T^{i+O(1)}(n)$ for some computable function $f$. The encoding of $(x, y)$ contains two parts: the encoding of $P$ with length $l(p)$, and the corresponding Shannon-Fano code. \hfill \square

**Lemma 7.5** For all $\Pi_1^0$-independence tests $d$, there is an $i$ such that $d^i \preceq d$.

**Proof** By universality of $m$ there exists a constant $c$ such that

$$-\log m(x) \leq n + 2\log n + c. \tag{12}$$

For any $n$, the values $d_s(u, v)$ can be evaluated for increasing $s$ and all $(u, v)$ with $l(u) = l(v) = n$ until a time $s = \tau(n)$ is found such that

$$\sum_{l(u) = l(v) = n} 2^{d_s(u, v) - 2n - 4\log n - 2c} \leq 1.$$

Such $s$ always exists because of (2), (10) and (12). Hence the “code length” function

$$cl(u, v) = -d_s(u, v) + 2n + 4\log n + 2c$$
defines a semimeasure \( P(u, v|n) = 2^{-cl(u,v)} \). The function \( \tau(n) \) that evaluates \( s \) for each \( n \) is computable, and by the above construction it has complexity \( K(\tau) \leq K(d) + O(1) \), so that \( \tau(n) \leq T^{K(d)+O(1)}(n) \). Therefore, a program \( p \) exists that computes \( \lceil -\log P(u, v|n) \rceil \) from \( n, u, v \) within time \( T^{K(d)+O(1)}(n) \), and \( l(p) \leq ^+ T K(d) + O(1) \). Therefore, a program \( p \) exists that computes \( \lceil -\log P(u, v|n) \rceil \) from \( n, u, v \) within time \( T^{K(d)+O(1)}(n) \), and \( l(p) \leq ^+ T K(d) + O(1) \). Let \( c \) be the constant from inequality (11). Lemma 7.4 shows that for some \( i = K(d) + c + O(1) \), we have:

\[
K^{i-c}(x, y|n) \leq ^+ K(d) + 2n + 4\log n - d_s(x, y).
\]

Inequality (11) shows:

\[
K^i(x, y) \leq 2n - d_s(x, y) + O(\log n).
\]

Hence for \((x, y) \in R\),

\[
d^i(x, y) = K(x) + K(y) - K^i(x, y)
\geq 2(n - \log n) - K^i(x, y)
\geq d_s(x, y) - O(\log n)
\geq d(x, y) - O(\log n).
\]

**Notation** From now on all constants implicit in the \( O() \) notation do not depend on \( i \), whereas constants implicit in the \( \leq^+ \) notation may be dependent on \( i \). For the proof of Lemma 7.9 we need Lemmas 7.6, 7.7 and 7.8.

**Lemma 7.6** For almost all \( i \) and all \( x, y \) with \( l(x) = l(y) = n \), we have:

\[
K^{i+O(1)}(x|n) + K^{i+O(1)}(y|x)
\leq^+ K^i(x, y|n)
\leq^+ K^{i-O(1)}(x|n) + K^{i-O(1)}(y|x).
\]

**Proof** The second inequality follows from combining minimal programs from the definition of \( K^{i-O(1)}(x|n) \) and \( K^{i-O(1)}(y|x) \) into one program producing \( \langle x, y \rangle \) from \( n \) in time \( T^i(n) \). It remains to prove the first inequality. For all \( i \) large enough, we do this by defining a semimeasure \( P(x, y|n) \) over all pairs of strings of length \( n \):

\[
P(x, y|n) = 2^{-K^i(x, y|n)}. \tag{13}
\]

The computable marginal and conditional semimeasures of \( P \) are:

\[
P(x|n) = \sum_{u: l(u) = n} P(x, u|n),
P(y|x) = P(x, y|n)/P(x|n). \tag{14}
\]

Both measures are computable and can be evaluated in time \( T^{i+O(1)}(n) \). Remark that the Kolmogorov complexity of these measures is bounded by \( K(T^i) + O(1) \leq^+ 0 \),
since constants that only depend on \(i\) are absorbed in the \(\leq^+\) notation. From Lemma 7.4 it follows that:

\[
\begin{align*}
K^{i+O(1)}(x|n) &\leq^+ - \log P(x|n), \\
K^{i+O(1)}(y|x) &\leq^+ - \log P(y|x).
\end{align*}
\] (15)

The first inequality of the lemma follows from combining (13), (14) and (15). \(\square\)

**Lemma 7.7** For almost all \(i\) and \(n\), there exist strings \(x\) and \(a\) such that:

- \(l(a) = l(x) = n\)
- \(K^{i+O(1)}(a|n) \leq^+ 0\)
- \(K(x|n) \geq^+ n\)
- \(K^i(a|x) \geq^+ n\).

**Proof** Let \(c\) be a large enough constant. Let \(a\) be the lexicographic first string of length \(n\) that cannot be produced from \(n\) by a program of length less than \(n\) in time less than \(T^{i+c}(n)\). There is always such a string \(a\). Obviously this string can be produced by running all possible programs for \(T^{i+c}(n)\) steps, and searching for the lexicographic first string of length \(n\) that not has been output. This program needs a computation time bounded by \(T^{i+2c}(n)\), for \(c\) large enough. To produce \(a\) from \(n\) in time \(T^{i+2c}(n)\), it suffices to have a description of \(T^{i+c}\) and execute a constant amount of instructions. By this, the second condition is satisfied, since \(K(T^{i+c})\) is absorbed in the \(\leq^+\) notation.

There is at least one binary string of length \(n\) with \(K(x|a) \geq n\). Pick one such string to be \(x\). Note that \(K(x|n) \geq^+ K(x|a) \geq n\), and by this the third condition is satisfied. By definition of \(a\) and \(x\) we find:

\[2n \leq^+ K^{i+c}(a|n) + K^{i+c}(x|a).\]

Let \(c_1\) and \(c_2\) correspond to the \(O(1)\) constants in \(K^{i+O(1)}\) and \(K^{i-O(1)}\) from Lemma 7.6. Apply Lemma 7.6 for \(i \rightarrow i + c_1\), and assume \(c \geq c_1 + c_2\):

\[2n \leq^+ K^i(x|n) + K^i(a|x).\]

Now it holds that \(K(x|n) \leq^+ n\) [10], hence for \(i\) large enough we have \(K^i(x|n) \leq^+ n\), and

\[2n \leq^+ n + K^i(a|x).\]

By this, the last condition is satisfied. \(\square\)

**Lemma 7.8** For any function \(f\) and any set \(N\), if

\[
\exists c \exists \infty n \in N \lfloor n - c \log n < f(n) \rfloor,
\]

then

\[
\forall c \exists \infty n \in N \lfloor c \log n < f(n) \rfloor.
\]
Proof Let \( c \) be a constant, and \( n_i, i \in \omega \) be an infinite increasing sequence witnessing the first expression. For any \( c' \), take \( j \) large enough such that \( n_j > (c + c') \log n_j \). Then the infinite sequence \( n_i, i \geq j \), satisfies the second inequality. \( \Box \)

**Lemma 7.9** For all \( i \), there is a \( j \), such that \( d_i \not\geq d_j \).

**Proof** We prove that there exists a constant \( c \) such that for all \( i \geq c \), \( d_i - c \not\geq d_{i+c} \). By the converse of the definition of R-domination it needs to be shown that:

\[
\forall c' \exists \infty (x,y) \in R[d_i - c(x,y)\not\geq d_i + c(x,y)].
\]

By Lemma 7.8, it suffices to prove that

\[
\exists c' \exists \infty (x,y) \in R[d_i - c(x,y) + n - c' \log n < d_i + c(x,y)].
\]

(16)

For any \( n \) large enough, pick \( x \) and \( a \) as in Lemma 7.7, and let \( y = \text{XOR}(x,a) \), where XOR is the bitwise exclusive-or operator. We now derive inequalities (17), (19), and (20).

- Note that XOR\((y, a) = \text{XOR}(\text{XOR}(x,a), a) = x \). This provides a program for \( x \) given \( a \) and \( y \). It follows that \( K(x) \leq K(y) + K(a | y) \) and hence:

\[
\begin{align*}
K(y) & \geq K(x) - K(a | y) \\
& \geq K(x) - K^{i+O(1)}(a | n) \\
& \geq K(x) \\
& \geq n.
\end{align*}
\]

(17)

It follows that \( (x, y) \in R \) for \( n \) large enough.

- Since XOR\((y, x) = a \), it follows that any program computing \( y \) from \( x \), also computes \( a \) from \( x \). The extra time for this computation is bounded by some computable function. Therefore, for some \( c' \) large enough:

\[
K^{i-c'}(y | x) \geq K^{i-c}(a | x) \geq n.
\]

(18)

Furthermore we have \( K^i(x) \geq n \). Hence, for \( c - c' \) large enough, Lemma 7.6 can be applied with \( i \to i - c \). Inequalities (11) and (18) imply:

\[
\begin{align*}
K^{i-c}(x,y) & \geq K^{i-c}(x | n) + K^{i-c'}(y | x) - O(\log n) \\
& \geq K(x | n) + n - O(\log n) \\
& \geq 2n - O(\log n).
\end{align*}
\]

(19)

- Since XOR\((x, a) = y \), it follows for \( c' \) large enough, that

\[
K^{i+2c'}(y | x) \leq K^{i+c'}(a | x) \leq 0.
\]
The last inequality follows from the second condition of Lemma 7.7. Remark that for \( i \) large enough, \( K^{i+2c'}(x) \leq^+ n + 2 \log n \). Assuming \( c - 2c' \) large enough, a bound for \( K^{i+c}(x, y) \) can be derived using Lemma 7.6 with \( i \to i + c \):
\[
K^{i+c}(x, y) \leq^+ K^{i+2c'}(x) + K^{i+2c'}(y|x) \\
\leq^+ n + O(\log n).
\] (20)

Combining inequalities (17), (19), (20), and \( K(x) \geq^+ n \), we obtain
\[
d^{i-c}(x, y) \leq^+ K(x) + K(y) - K^{i-c}(x, y) \\
\leq^+ O(\log n),
\]
\[
d^{i+c}(x, y) \geq^+ K(x) + K(y) - K^{i+c}(x, y) \\
\geq^+ n - O(\log n).
\]

Hence the constructed pair \((x, y) \in R\) satisfies
\[
d^{i-c}(x, y) + n - O(\log n) \leq^+ d^{i+c}(x, y).
\] (21)

Such a pair can be constructed for every large enough \( i \) and \( n \). This proves statement (16).

\[\square\]

**Corollary 7.10** Algorithmic mutual information

\[I(x; y) = K(x) + K(y) - K(x, y)\]

is an independence test that R-dominates all \( \Pi_1^0 \)-independence tests.

**Proof** Because \( K(x, y) = \inf_i \{K^i(x, y)\} \) it follows that:
\[I(x; y) = \sup_i \{d^i(x, y)\}.
\]

By Lemma 7.5 it R-dominates all \( \Pi_1^0 \)-independence tests.

\[\square\]

**Corollary 7.11** There exists a constant \( c \), such that for all \( \Sigma_1^0 \)-semimeasures \( P, Q \), there exist a \( \Pi_1^0 \)-independence test \( d \) for \( P, Q \) such that \( d(x, y) \geq n - c \log n \) for infinitely many \((x, y)\) with \( l(x) = l(y) = n \).

**Proof** For some \( i \) large enough, there are infinitely many \( x, y \) with \( l(x) = l(y) \) and
\[d^{i}(x, y) \geq n - c \log n - c_i,
\]
where \( c_i \) is the constant implicit in the \( \leq^+ \) notation of (21). By universality of \( m \), we have that \( P(x) \leq 2^{c_P} m(x) \) and \( Q(x) \leq 2^{c_Q} m(x) \), for some constants \( c_P, c_Q \). Remark that \( d(x) = d^i(x) - c_P - c_Q \) satisfies inequality (2), and is therefore a \( \Pi_1^0 \)-independence test for \( P, Q \). For \( \log n > c_i + c_P + c_Q \) and infinitely many \( x, y \) with \( l(x) = l(y) \) we have:
\[d(x, y) \geq n - (c + 1) \log n.
\]

\[\square\]
From the proof it also follows that

**Corollary 7.12** There is a constant $c$, such that for all $\Pi^0_1$-independence tests $d$, there is a $\Pi^0_1$-independence test $d'$ with

$$d'(x, y) - d(x, y) \geq n - c \log n,$$

for infinitely many $x$, $y$ with $l(x) = l(y) = n$.

**Proof** Note that for $i = K(d) + O(1)$ we have

$$d^i(x, y) - d(x, y) \geq n - c \log n - c_i.$$

Hence for all $n$ with $\log n \geq c_i$ we have

$$d^i(x, y) - d(x, y) \geq n - (c + 1) \log n.$$
