(Received 20 October 2008; published 13 August 2009)

We consider an interface between two non-Abelian quantum Hall states: the Moore-Read state, supporting Ising anyons, and the \( k = 2 \) non-Abelian spin-singlet state, supporting Fibonacci anyons. It is shown that the interface supports neutral excitations described by a \((1 + 1)\)-dimensional conformal field theory with a central charge \( c = 7/10 \). We discuss effects of the mismatch of the quantum statistical properties of the quasiholes between the two sides, as reflected by the interface theory.

DOI: 10.1103/PhysRevLett.103.076803 PACS numbers: 73.43.Cd

The quantum statistics of particles confined to two spatial dimensions is not confined to be either bosonic or fermionic. Particles called (Abelian) anyons pick up phase factors upon braiding, while for non-Abelian anyons braiding is represented by nontrivial matrices acting on multi-component wave functions or state vectors. Non-Abelian anyons offer most exciting perspectives for what is called topological quantum computation (TQC) \([1,2]\). The idea is that a collection of non-Abelian anyons, realized as excitations in a suitable quantum medium, open up a quantum register whose dimension depends on the number and the type of the anyons. This register can then be manipulated via a braiding of world lines of the anyons, leading to quantum logic gates.

The leading candidate for physical systems that can support non-Abelian anyons is specific fractional quantum Hall (QH) liquids. Current experimental investigations seek to confirm the tentative identification of the state underlying QH plateau observed at filling fraction \( 5/2 \) with the Moore-Read (MR) state \([3]\), or a close relative thereof \([4,5]\). This state is known to support non-Abelian anyons of so-called Ising type, the name deriving from an underlying algebraic structure which it has in common with the 2D Ising model at criticality. The braiding matrices for Ising anyons are nontrivial, but they fall short of allowing universal TQC.

The other prototypical class of non-Abelian anyons is the so-called Fibonacci anyons. Their name derives from the fact that the dimensionality of the quantum register for an \( n \)-anyon state is the \( n \)th entry in the famous Fibonacci sequence \( f_n = 1, 2, 3, 5, \ldots, f_n = f_{n-1} + f_{n-2} \). Matrices generated by successive braidings of such Fibonacci anyons are dense in the unitary group, implying that they are universal for TQC. All logic operations on the quantum register can be approximated to arbitrary accuracy by successive braidings (see, for example, \([6]\)).

Two relatively simple quantum Hall states are known to support Fibonacci anyons (see, e.g. \([7]\)). The first is the so-called Read-Rezayi state with order \( k = 3 \) clustering, at filling \( \nu = 3/5 \) (possibly related to a quantum Hall plateau observed at \( \nu = 12/5 \)). The other is the \( k = 2 \) non-Abelian spin-singlet (NASS) state proposed by Ardonne and one of the present authors in 1999 \([8]\), at filling \( \nu = 4/7 \). In many ways, this NASS state is similar to the MR state, the main difference being that it describes two species of fermions, which can be the spin-up and spin-down states of spin-1/2 electrons.

For general quantum Hall liquids, an edge separating the liquid from vacuum carries one or more gapless modes, described by a chiral conformal field theory (CFT). There is always a charge mode, which is responsible for the low-energy transport properties characteristic of quantum Hall liquids. A non-Abelian state has neutral edge modes, which can be linked to the fusion channel degeneracies of the bulk non-Abelian state. For the MR state these neutral modes are a Majorana (Ising) fermion (CFT with central charge \( c = 1/2 \)) while for the \( k = 2 \) NASS state the neutral modes are particular parafermions [descending from an \( SU(3) \) structure, with a CFT central charge \( c = 6/5 \)]; see \([7–9]\) for details.

In this Letter we consider an interface between the MR liquid (supporting Ising anyons) and the \( k = 2 \) NASS liquid (supporting Fibonacci anyons) and we investigate how the mismatch between the underlying topological orders plays out in the properties of this interface. We establish that the interface supports gapless neutral modes described by a specific CFT of central charge \( c = 7/10 \). Dragging a Fibonacci anyon through this interface turns it into an Ising anyon, in the process exciting a specific \((\hbar = 3/80)\) neutral interface mode. We also investigate to what extent processes where neutral bulk excitations tunnel to and from the interface can relax the internal state of qubits spanned by pairs of quasiholes.

For a MR-NASS interface to be possible experimentally, it will be necessary to have electronic interactions such that both the MR state (in the polarized case) and the NASS states (in the unpolarized case and at zero Zeeman splitting) represent stable phases. Exact diagonalization studies \([10]\) in the second Landau level (LL) indicate that it is indeed possible to modify the Coulomb interaction such that both the MR and the NASS wave functions (for up to \( N = 12 \) particles) have high overlaps.
The Virasoro primaries coordinate to two groups, each containing where the sum is over all inequivalent ways of dividing the MR and NASS wave functions (at filling \( \nu = 1 \) and \( \nu = 4/3 \), respectively). Their fermionic counterparts at \( \nu = 1/2 \) and \( \nu = 4/7 \) are obtained by multiplication with an overall Jastrow factor \( \prod c_i(z_i - z_j) \). The bosonic MR and NASS wave functions can be characterized as the maximal density, zero-energy eigenstates of [11]

\[
H = \sum_{i<j<k} \delta^{(2)}(z_i - z_j) \delta^{(2)}(z_i - z_k).
\]

For the NASS states the coordinates \( \{z_i\} \) split as \( \{z_i^+, z_i^-\} \).

The MR wave function can be written as

\[
\Psi_{MR} = \frac{1}{\mathcal{N}} \sum_{S_1, S_2} \prod_{i<j \in S_1} (z_i - z_j)^2 \prod_{k<l \in S_2} (z_k - z_l)^2,
\]

where the sum is over all inequivalent ways of dividing the \( N \) coordinates into groups \( S_1, S_2 \) with \( N/2 \) coordinates each. In a similar way, the bosonic NASS wave function for \( N_1 \) spin-down particles and \( N_1 \) spin-up particles is

\[
\Psi_{NASS} = \frac{1}{\mathcal{N}} \sum_{S_1, S_2} \Psi_{S_1}^{(2)}(z_i^+, z_i^-) \Psi_{S_2}^{(2)}(z_i^+, z_i^-),
\]

where the sum is over all inequivalent ways of dividing the coordinates to two groups, each containing \( N_1/2 \) spin-up and \( N_1/2 \) spin-down, and

\[
\Psi_{S_1}^{(2)}(z_i^+, z_i^-) = \prod_{i<j \in S_1} (z_i^+ - z_j^-)^2 \prod_{p<q \in S_2} (z_p^+ - z_q^-)^2 \prod_{i,j \in S_1} (z_i^+ - z_j^-)^2.
\]

**Ising and Fibonacci anyons.**—For Ising anyons there are three particle types, \( I, \psi, \) and \( \sigma \), with fusion rules

\[
\psi \times \psi = I, \quad \sigma \times \psi = \sigma, \quad \sigma \times \sigma = I + \psi.
\]

In addition, \( I \times x = x \) for \( x = I, \psi, \sigma \). For Fibonacci anyons there are only two particle types, \( I, \phi \), and

\[
I \times I = I, \quad I \times \phi = \phi, \quad \phi \times \phi = I + \phi.
\]

The Virasoro primaries \( I, \psi, \) and \( \sigma \) in the \( c = 1/2 \) Ising CFT, of conformal dimensions \( h_\psi = 1/2, h_\sigma = 1/16 \), are in direct correspondence with the particle types \( I, \psi, \) and \( \sigma \). The relation between the Fibonacci particle types \( I \) and \( \phi \) and the \( c = 6/5 \) parafermion theory is more subtle. The parafermion CFT has eight fields that are primary with respect to the parafermion chiral algebra: the identity \( I \), three \( h = 1/2 \) parafermion fields \( \psi_1, \psi_2, \phi_1 \), three \( h = 1/10 \) spin fields \( \sigma_1, \sigma_2, \sigma_3 \), and the \( h = 3/5 \) spin field \( \rho \). The correspondence is

\[
I \leftrightarrow \{I, \psi_1, \psi_2, \phi_2\}, \quad \phi \leftrightarrow \{\sigma_1, \sigma_2, \sigma_3, \rho\}.
\]

A further subtle point is that the parafermion sector denoted as “\( \rho \)” contains two leading Virasoro primaries \( \rho_c \) and \( \rho_s \), of dimension \( h = 3/5 \). The Virasoro fusion rule \( \sigma_1 \sigma_3 = [1 + \rho_s] \) shows that \( \rho_s \) acts as fusion channel changing operator for two \( \sigma_i \) fields, which correspond to the spinless quasiholes over NASS state. Similarly, the fusion rule \( \sigma_i \sigma_1 \psi_1 = [1 + \rho_c] \) shows that \( \rho_c \) changes the fusion channel for fields \( \sigma_1 \) and \( \psi_1 \), which come with spin-full quasiholes. We refer to [7] for a complete description of the fusion rules and operator product expansions in the \( c = 6/5 \) CFT.

**Quasihole counting formulas and edge characters.**—Our strategy for obtaining the partition sum for a MR-NASS interface theory will be by reduction from a counting formula for quasihole degeneracies in spherical geometry (“giant hole approach”). In the presence of \( N_\phi \) flux quanta piercing through the sphere, the LLL orbitals form an angular momentum multiplet with \( L = N_\phi/2 \), with, up to stereographical projection, the wave function \( \rho^m \) corresponding to the orbital with \( L_z = m - N_\phi/2 \), for \( m = 0, \ldots, N_\phi \). The Hamiltonian Eq. (1) acts on many-body wave functions with \( N_1, N_1 \) spin-up and spin-down electrons present. For \( N_1 = 1 \) and flux \( N_\phi = \frac{5}{2} N \) there is a unique zero-energy eigenstate, which is the bosonic NASS state whose asymptotic filling is \( \nu = 4/3 \). If we now add \( \Delta N_\phi \) extra flux quanta and unbalance the numbers of up and down electrons, we create \( n_1, n_1 \) spin-up and spin-down quasiholes, with \( n_1 + n_1 = 4 \Delta N_\phi, n_1 + n_1 = N_1 + n_1 \).

The zero-energy quasihole states in the presence of \( \Delta N_\phi \) are degenerate for two reasons. The first is a choice of orbital for the quasiholes and the second is a choice of fusion channel. The full structure of the space of zero-energy states is captured by a zero-energy quasihole partition sum \( Z_{\text{sphere}}[N_1; n_1, n_1](q) = \text{tr}_{E=0}[q^{L_z}] \). For the Laughlin and MR states, expressions for \( Z_{\text{sphere}}(q) \) have been given in [12]. For the \( k = 2 \) NASS the following expression was obtained in [9]:

\[
\sum_{\substack{F_1 = n_1, n_1 \mod 2 \\ F_2 = n_1 + n_1 \mod 2}} q^{(F_1^2 + F_2^2 - F_1 F_2)/2} \binom{n_1 + F_1}{F_1} q^{(n_1 + F_1)/2} \binom{n_1 + F_2}{F_2} q^{(n_1 + F_2)/2} \binom{n_1}{n_1} \binom{n_1 + F_1}{n_1} \binom{n_1 + F_2}{n_1}.
\]

The \( q \) binomial is [here \( (q)_n = (1-q)(1-q^2)\cdots(1-q^n) \)]

\[
\binom{n}{m} = \frac{(q)_n}{(q)_m(q)_{n-m}}.
\]

Putting \( N_1 = N, N_1 = 0, n_1 = n, n_1 = N + n \), the formula reduces to the case of the \( N \)-particle MR state with \( n \) quasiholes,
\[
\sum_{F_r, F_s=0,2,4, \ldots} q^{F_r^2/2} \left( \frac{n}{2} \right)_q \left( \frac{F_s}{F_r} \right)_q, \tag{12}
\]

This expression coincides with a finitized chiral character for the vacuum sector in a \( c = 7/10 \) minimal model of CFT [13]. We conclude that the MR-NASS interface supports neutral excitations described by this precise CFT [Table I] [15].

The fields of the CFT at \( c = 6/5 \) can be written as a direct product of fields of the CFTs at \( c = 7/10 \) and \( c = 1/2 \). We identify the correspondence by the use of a character formula and through the discrete symmetries associated with the fields. This requires one to consider an extended algebra produced by explicitly adding a fermion parity operator to both the \( c = 7/10 \) and the \( c = 1/2 \) theories, \((-1)^F\) and \((-1)^F\), which satisfy \((-1)^F, \epsilon^0 = 0\) and \((-1)^F, \psi \epsilon^0 = 0\). The Ramond sector is then effectively “doubled,” so \( \sigma, \tilde{\sigma}, \text{and} \tilde{\sigma}' \) are replaced, respectively, by \( \sigma \pm, \tilde{\sigma} \pm, \text{and} \tilde{\sigma} \pm \), each having a well-defined fermion parity given by the subscript. Their fusion rules are now constrained so that fermion parity is respected.

The fields are related through the following relations:

\[
\begin{align*}
\sigma_1 &= \tilde{\sigma}_+ \otimes \sigma_+ + \tilde{\sigma}_- \otimes \sigma_- + \sigma_+ \otimes \tilde{\sigma}_-, \\
\sigma_2 &= \epsilon^0 \otimes \psi, \\
\rho &= \epsilon^0 \otimes \psi, \\
I &= \epsilon^0 \otimes \psi + I \otimes I,
\end{align*}
\tag{13}
\]

where the notation \( \phi_1 \otimes \phi_2 \) describes a direct product of a field in the \( c = 7/10 \) theory (\( \phi_1 \)) and a field in the \( c = 1/2 \) theory (\( \phi_2 \)). In addition, the two Virasoro primaries \( \rho_\sigma \) and \( \rho_c \) have the following decompositions:

\[
\begin{align*}
\rho_\sigma &= \epsilon^0 \otimes \psi, \\
\rho_c &= \epsilon^0 \otimes I.
\end{align*}
\tag{14}
\]

A physical way of viewing the creation of the \( c = 7/10 \) edge between the MR state and the NASS state is by starting with counterpropagating edges, with \( \tilde{c} = 1/2 \) and \( c = 6/5 = 1/2 + 7/10 \), respectively, and introducing tunneling between the two edges. As the tunneling increases, the counterpropagating Majorana fermions gap out, leaving behind only the \( c = 7/10 \) edge. It is useful in this case to consider an inverted form of Eq. (13), which contains explicitly both counterpropagating modes. In this way, one can identify those degrees of freedom which gap out and those which remain behind. For example, at the level of the characters the following relation holds:

\[
\begin{align*}
\check{\psi} \eta_{12} + \tilde{I}_{1/2} I_{6/5} &= I_{7/10} (\check{\psi} \eta + \tilde{I}_{1/2} I_{1/2}) \\
&+ \epsilon^0 (\check{\psi} I_{1/2} + \tilde{I}_{1/2} \psi).
\end{align*}
\tag{15}
\]

Here \( I_{1/2}, I_{7/10}, \text{and} I_{6/5} \) are the identity fields for the three theories. The combinations of fields appearing within parentheses gap out when an effective mass term \( m \psi \check{\psi} \psi \) is generated by tunneling, leaving only the \( c = 7/10 \) degrees of freedom behind on the edge.

Gedanken experiments.—To illustrate the role of the \( c = 7/10 \) interface as a “mediator” between two regions of
We close by mentioning some ideas related to the work presented here. The authors of [17] discuss how condensing a boson can transform a non-Abelian topological phase (NA) into a phase with different topological order (NA'). This construction naturally leads to properties of a NA-NA' interface. In [18] a finite density of non-Abelian anyons is shown to nucleate a different topological liquid within a “parent” non-Abelian liquid. Their interface is shown to provide examples of edge states between non-Abelian phases. Clearly, the various approaches to NA-NA' interfaces are complementary, and they illustrate distinct features of the underlying physics.

We thank E. Ardonne, F. A. Bais, and A. W. W. Ludwig for discussions and for sending us their manuscripts prior to publication. This work was supported by the foundation FOM of the Netherlands and by the ICMT.

---

[15] We have identified the interface excitations in a physical picture where the 2-fluid configuration is generated from a NASS state by accumulating spin-down quasiholes near the south pole on the sphere. A possible strategy towards experimental realization of a MR-NASS interface will be rather the opposite: start from the polarized MR state, reduce Zeeman splitting by applying hydrostatic pressure, and then increase the filling, so as to nucleate islands of the NASS phase in the MR background.
