Quasiperiodicity and 2D Topology in 1D Charge Ordered Materials

Felix Flicker and Jasper van Wezel
H. H. Wills Physics Laboratory, University of Bristol, Tyndall Avenue, Bristol, BS8 1TL, UK

It has recently been argued that individual 1D quasicrystals can be ascribed 2D topological quantum numbers and a corresponding set of topologically protected edge modes. Here, we demonstrate the equivalence of such 1D quasicrystals to a mean-field treatment of incommensurate charge order in 1D materials. Using the fractal nature of the spectrum of commensurate charge-ordered states we consider incommensurate order as a limiting case of commensurate orders. We show that their topological properties arise from a 2D parameter space spanned by both phase and wave vector, bringing the observation of 2D edge modes in line with the standard classification of topological order. The equivalence also provides a set of real-world quasiperiodic materials which can be readily experimentally examined. We propose an experimental test of both the quasicrystalline and topological character of these systems in the form of a quantized adiabatic particle transport upon dragging the charge-ordered state.

The second half of the twentieth century saw two revolutions in condensed matter physics. The first began with the mathematical observation that solids need not involve periodic repetitions of unit cells, but can instead involve aperiodic tilings of two or more inequivalent cells[1]. Experimental verification in the form of a ‘quasicrystalline’ Al-Mn alloy followed shortly afterwards[2].

The second revolution regarded the observation and subsequent theoretical characterization of the quantum Hall effect[3, 4]. This prompted the realization that phase transitions cannot all be characterized solely in terms of the continuous symmetries they break. It lead to a new, topological, classification scheme of all non-interacting fermion theories according to discrete symmetries, in what has come to be known as the ‘Tenfold Way’[5, 6].

Recently these two cornerstones of modern condensed matter physics have been shown to be mathematically linked through the ubiquitous Harper equation[7]. This equation has long been known to govern electrons on a 2D lattice in the presence of a magnetic field, i.e. the quantum Hall effect[8]. It was also recently shown to provide a description of 1D quasicrystals when used to describe electrons in a 1D lattice with an incommensurate periodically modulated on-site potential[9]. Based on the equivalence of the underlying mathematical structures of these two systems, quantized transport properties analogous to the quantum Hall conductance were predicted for the quasicrystal, and subsequently observed in an experimental realization using optical waveguides[10].

The possibility of ascribing 2D quantum numbers to a system with 1D quasicrystalline order contradicts the prediction of the Tenfold Way, and consequently has been widely heralded as evidence of the effectively higher-dimensional origin of quasicrystalline states[10][15]. This interpretation, however, was recently called into question by Madsen et al., who instead argue that the waveguide experiments involve a second degree of freedom which generates a family of quasicrystals[16]. The resulting parameter space is therefore 2D, and the topological quantum number should be assigned to the entire 2D family of related quasicrystalline states[16].

In this letter we propose that a natural resolution to this disagreement can be found by applying the Harper equation to the description of charge order in (quasi-)1D materials. As in the case of optical waveguides, we find that a mean-field description of the charge-ordered state at different electronic filling fractions can be labeled by the same set of topological quantum numbers as the 2D quantum Hall effect. We further demonstrate that the incommensurate charge-ordered state indeed has a quasicrystalline character.

In contrast to the optical waveguide implementation, however, the charge-ordered system allows for the interpretation of quasicrystalline order as the limiting case of a sequence of different crystalline orders. This fact enables us to explicitly identify a second degree of freedom, the phase of the order parameter, which generates a family of 1D charge-ordered states. It is this 2D family of states that can be classified by 2D topological quantum numbers. In addition, we show that the topological classification of charge-ordered materials is robust against effects beyond the mean-field level, and we propose experimental tests of both the topological character of charge-ordered 1D materials and their equivalence to quasicrystals. These tests provide experimental access to a novel type of quantized adiabatic particle transport.

Quasicrystals—Quasicrystals are defined to be quasiperiodic tilings of two (or more) inequivalent unit cells[1]. A quasiperiodic tiling in 1D can be generated from the projection of a regular 2D crystal[1]. As shown in Figure[1] a straight line can be drawn in a square 2D lattice, in such a way that it hits exactly one lattice point. A second line is then drawn parallel to the first, going through the opposite corner of the unit cell. Whenever a point of the 2D lattice falls between the lines, its projection onto the first line forms a site of the 1D quasicrystalline lattice. The projected lattice consists of precisely two unit cells, of different sizes. These appear to be randomly tiled, in a never-repeating
A pair of parallel lines are overlaid on the square lattice, in such a way that they hit only a single pair of lattice points on opposing corners of one of the square unit cells. The lattice points between the lines are then projected, and form the sites of the 1D quasicrystal. The inequivalent cells in the quasicrystalline lattice are colored red and blue for clarity. A remnant of the 2D projection underlying the 1D quasicrystal can be seen in its diffraction pattern, which is generated by two different reciprocal lattice vectors. This argument was recently employed to explain the observation of an integer number of edge states in 1D quasicrystals realized in optical waveguide arrays. The combined system can be interpreted as a quasicrystal, which could in principle be observed in scanning tunneling microscopy experiments. By continuously shifting the charge order with respect to the atomic lattice, a continuous set of locally isomorphic quasicrystals is generated. The emergence of charge-ordered states can be most easily understood in a model of spinless fermions hopping on a 1D lattice, in the presence of nearest-neighbor density-density interactions (strength $h$). Such a 1D system is always unstable towards a spontaneous modulation of its local electronic density. This can be described at the mean-field level by introducing the expectation value $\Delta Q(h) = 2h \sum_k \langle \hat{c}_k^\dagger \hat{c}_{k+Q} \rangle$, where $Q$ is a wave vector connecting the two points on the Fermi surface of the 1D band structure. Using this decoupling, the mean-field Hamiltonian can be written as:

$$
\hat{H} = \sum_{0 \leq k < 2\pi/a} \left\{ \frac{1}{2} \epsilon_k \hat{c}_k^\dagger \hat{c}_k + \Delta_Q \hat{c}_k^\dagger \hat{c}_{k+Q} + H.c. \right\}
$$

where $\epsilon_k = 2t (1 + \cos (ka)) - \mu$ describes the bare band structure resulting from the hopping integral $t$ and chemical potential $\mu$, and the charge density order parameter can be written as $\Delta_Q = |\Delta_Q| \exp (i\theta)$. If the chemical potential is tuned to a rational fraction $p/q$ of the bare bandwidth $4t$, the charge order in the ground state of the full mean-field Hamiltonian in Equation (1) will have period $qa$. Working in a reduced Brillouin zone of length
2π/qα, the Hamiltonian can then be rewritten as:

\[
\hat{H} = \sum_{0 \leq k < 2\pi/q\alpha} \left( \hat{c}_{k+Q}^{\dagger} \hat{c}_{k+Q} \cdots \hat{c}_{k+2Q}^{\dagger} \right) H_k \left( \begin{array}{c} \hat{c}_{k+Q} \\ \hat{c}_{k+2Q} \\ \vdots \\ \hat{c}_{k+qQ} \end{array} \right)
\]

\[
H_k = \begin{pmatrix} \epsilon_{k+Q} & \Delta_Q & 0 & \cdots & 0 & \Delta_Q^* \\ \Delta_Q^* & \epsilon_{k+2Q} & \Delta_Q & 0 & \cdots & 0 \\ 0 & \Delta_Q & \ddots & \ddots & \vdots \\ \vdots & 0 & \ddots & \ddots & \ddots \\ 0 & \cdots & 0 & \Delta_Q & \epsilon_{k+qQ} \end{pmatrix}.
\]

For the case |ΔQ|/t = 1 this is precisely the matrix form of Harper’s equation, applied by Hofstadter to the 2D electron gas in the presence of a magnetic field \[8\]. A plot of the eigenvalues against filling fraction has come to be known as Hofstadter’s butterfly (Figure 2). The eigenvalues of the matrix in Equation 2 constitute the possible energies of the system after the charge order has been established. In the presence of a charge modulation with period qα, the energies form q sub-bands, separated by energy gaps \[23\].

The contribution of each filled sub-band to the overall conductivity of the system is quantized in units of 2πe²/h \[4\]. The quantization of conductance can be understood by realizing that the phase, θ, signifying the position of the charge modulation relative to the atomic lattice, is not fixed by the mean-field solution of Equation 2. The band structure can thus be drawn within a 2D space spanned by θ and kα, as indicated on the right of Figure 2 for the case p/q = 1/3. Each of these 2D sub-bands can be assigned a topological quantum number, the Chern number C₁, by integrating the Berry curvature over this 2D space. In this specific problem C₁ can also be found by solving a Diophantine equation \[4\] \[25\]. The quantized conductance is then the sum of the Chern numbers for all occupied sub-bands \[4\]. In the quantum Hall effect, the Hall conductivity σ_{xy} is given by (2πe²/h)C₁. In the present case, the response function associated with the topological invariant is instead a ‘quantized adiabatic particle transport’ \[26\] \[27\]: adiabatically cycling θ through a full period results in the transfer of an integer number C₁ of electrons across the length of the 1D chain. Since θ describes the position of the charge modulation with respect to the atomic lattice, this cycling of θ corresponds to rigidly sliding the charge-ordered state through a single wavelength.

The Chern numbers for the commensurate charge-ordered patterns which make up the left of Figure 2 are indicated by its color scale. Only commensurate charge density modulations appear in the figure, but properties of the incommensurate charge-ordered states can be inferred from its large-scale structure. In particular, approaching an irrational value of the filling fraction as the limit of a series of rational fillings, it is clear that there must be large gaps (for example at the wings of the butterfly) even for incommensurate charge density modulations. We can then use the self-similarity of the fractal to see that any incommensurate state at irrational filling fraction η in Figure 2 must have the same nonzero sum of Chern numbers for its filled bands as the state with commensurate order at the rational filling p/q = η - ε, with ε → 0, which approaches η arbitrarily closely. For example, a close inspection of the underside of the butterfly’s lower left wing reveals a constant lining of C₁ = 1 for all commensurate states filled up to the wing, which must therefore also apply to the incommensurate states interpolating between them.

The Chern numbers characterizing the quasicrystalline state can take on any integer value depending on the value of the (irrational) filling fraction. This observation does not contradict the usual topological classification, as the Berry curvature giving rise to the Chern numbers is integrated over both k and θ, so that the relevant parameter space is 2D. The quantized transport and the corresponding edge states are properties of the entire 2D family of locally isomorphic charge-ordered states related by translations over θ, in direct analogy to the case of the optical waveguide experiments \[10\] \[16\].

**Experimental Realization** — In the analysis of the spectrum of Equation 2 we imposed a fixed value of ΔQ(h), and did not take into account the self-consistency condition ΔQ(h) = 2h \[\Theta(h)\] \[k\]. Although the self-consistency requirement can affect the sizes of the differ-
FIG. 3. **Left:** the allowed energies (scale truncated at $[-2.5t, 2.5t]$) as a function of filling fraction $p/q \in (0, 1)$, $q \in [2, 18]$ for the self-consistent solution of Equation (1) with $h = t$. Each sub-band is adiabatically connected to the corresponding sub-band in Figure 2. This implies that the sums of Chern numbers of filled sub-bands, indicated by the color scale, are the same. **Right:** the Berry curvatures (color coded and displaced for clarity) for the three sub-bands at 1/3 filling. Although the shapes are different to those in Figure 2, the integrals over them remain 1, −2, 1 in units of $2\pi$.

ent gaps in Figure 2, the topology of the sub-bands should not be affected, as none of the gaps can be closed up entirely. This implies that the Chern numbers characterizing the contribution of each sub-band to the adiabatic transport will be protected. Solving Equation (1) self-consistently, we obtain the allowed energies and Chern numbers displayed in Figure 3 [4, 25]. As expected, the value of $C_1$ associated with each sub-band is unaltered by deformations of $\Delta$ [28]. The self-consistent solution at a given interaction strength $h$ therefore has the same topology as the standard Hofstadter case of Figure 2.

Real materials cannot maintain the infinite fine structure of a fractal band. Instead, the gaps separating consecutive sub-bands will be closed when they become of the order of the effective energy scale set by local impurities, disorder, or lattice defects. When this happens, the Chern numbers of the two merging bands are added together to yield the Chern number describing the combined sub-band [28]. The larger gaps that correspond for example to the wings of the butterfly may be expected to survive in clean enough systems at low temperatures. For the corresponding filling fractions, the sum of Chern numbers must then still be nonzero, even for incommensurate charge-ordered states in the presence of defects and disorder.

A second effect of the presence of impurities in real materials is their ability to pin the charge order in place, inhibiting the freedom of the modulated pattern to slide along the atomic lattice. It is well established, however, that an applied voltage may be used to overcome the pinning potential in incommensurate charge-ordered materials, allowing them to conduct even in the presence of pinning centers [23, 29, 31]. The current produced in such a way includes both the effects of adiabatic particle transport originating in the band topology, and the effects of non-adiabatic band-mixing. Since we are here only interested in the former effect, we propose an alternative way of accessing the quantized particle transport in both commensurate and incommensurate charge-ordered states, based on the use of atomic condensates in optical lattices [32]. Such systems are more readily controllable and defect-free than 1D chains in actual materials. Indeed, the Harper equation has recently been realized in a cold atom setup [28]. Impurities (including the confinement potential) will inevitably exist, but we propose to use them to our advantage. An impurity can be simulated by altering the potential on a single site, providing for example an attractive center which locks one of the maxima of the charge density modulation into place. Provided that this intentional pinning does not disrupt the large-scale gap structure, the topology of the sub-band remains unaffected. By manipulating the impurity location, the charge density modulation can be dragged along the optical lattice, continuously cycling the value of $\theta$ along its entire range. As the corresponding charge-ordered pattern moves through one wavelength, it should be possible to measure the transport of an integer number ($C_1$) of electrons across the length of the optical lattice.

**Conclusions** - In this letter we have shown the equivalence between families of 1D locally isomorphic quasicrystals and a mean-field model of incommensurate charge order in 1D materials. Both exhibit the same set of topological quantum numbers normally ascribed to 2D systems, in agreement with recent results on optical waveguide experiments [9, 13]. Using the self similarity of the fractal pattern of allowed energies to interpret incommensurate charge-ordered materials as the limit of a series of commensurate cases, it becomes clear that these Chern numbers arise from an integral of the Berry curvature over a 2D space covering the entire family of locally isomorphic charge-ordered states. It is therefore the family of modulation patterns, rather than any individual quasicrystalline state, which is characterized by a 2D topological quantum number [10].

We find no conceptual difference between the topologies of the sub-bands for commensurate and incommensurate charge order, in the sense that the properties of an incommensurate charge-ordered state can be determined from the limit of a series of commensurate phases using the large-scale structure of the Hofstadter spectrum. The topological properties of the system survive in the full self-consistent solution of the model, and are robust against the inclusion of weak fluctuations, defects and impurities. The large-scale structure of the Hofstadter spectrum guarantees the possibility of quantized adiabatic particle transport in charge-ordered materials, as long as the gap size remains nonzero.

Finally, we propose an experimental test of the topological properties of charge-ordered materials by exploiting the possibility of directly controlling the phase of a
charge density modulation in atomic condensates in optical lattices. We predict that dragging the phase through a full period by this method will lead to the transfer of a quantized number of electrons across the system, providing a novel standard of conductance.

[24] Our image is a slight variation on Hofstadter’s since we discard non-coprime fractions. An example is $p/q = 1/2$ which has 2 bands in our case but is a solid line in Hofstadter’s. Our color coding also implies a slight variation on statements made for example in Reference [28]: for $1/4$ filling the central bands touch, so their Chern numbers should be added. We note that in our case higher harmonics of the charge order would couple the relevant sub-bands and cause a splitting.
[32] We address the issue of quantized adiabatic particle transport in quasi-1D materials in an upcoming paper.
