We present investigations of the optical gain cross section of 1.54 μm Er-related emission at 4.2 K in Si/Si:Er molecular-beam-epitaxy-grown multinanolayers. This ultranarrow (full width at half maximum below 8 µeV) emission originating from the unique Er-related optical complex, Er-1 center, ensures the best condition to achieve stimulated emission. The experiments were carried out using a combination of the variable stripe length and shifting excitation spot techniques under pulsed and continuous-wave excitations. The comparison of results for both excitation regimes enables to estimate an optical gain within the strong optical losses due to the free carrier absorption. Based on these measurements, the upper limit of the optical gain cross section of 10⁻¹⁷ cm² and the gain coefficient of 8.8 cm⁻¹ are deduced.

I. INTRODUCTION

Realization of Si-based optical amplifiers and lasers continues to be the major challenge of Si photonics. Recent advances in this field include Si Raman laser, visible laser based on Eu-doped GaN thin films on silicon, and microring cavity laser. These approaches, however, require external optical pumping for their operation or employ complicated manufacturing procedures. Rare-earth ion doped of Si, on the other hand, would be preferable due to relatively simple implementation into the existing Si technology and the attractive emission wavelength. Particularly interesting is Er-doped crystalline Si (c-Si:Er), where the radiative transition from the first excited state (4I₁₃/₂) to the ground state (4I₅/₂) of Er³⁺ ions is coincident with the absorption minimum of silica fibers (c-band; 1520–1570 nm), currently used in telecommunication networks. In spite of large research efforts, efficient amplifiers and lasers based on c-Si:Er have not yet been reported. The major problems are related to (i) the low solubility of Er in c-Si, (ii) thermal quenching, and (iii) inhomogeneous broadening of emission spectra due to multiplicity of Er-related optical centers formed in the Si host. The latter creates a situation when a photon emitted from a certain Er-related optical center is not in resonance with transitions of another center with somewhat different energy-level structure. This, together with a small absorption cross section of Er³⁺, creates a big hurdle, and even a doubt on the possibility of realization of optical amplification in c-Si:Er.

In this situation, the unique Er-related optical complex in Si/Si:Er multinanolayer structures brings a promise of optical amplification. The characteristic Er-related photoluminescence (PL) spectrum from these structures at 4.2 K features only few intense and ultranarrow lines (Fig. 1). On the basis of detailed analysis of this spectrum, formation of a single type of optically active center (labeled Er-1) has been conclusively established. When compared with broad spectra (~30 meV), typical for Er³⁺ ions in c-Si and large band-gap materials [e.g., semi-insulating polycrystalline silicon, SiO₂, ZnO, and GaN (Ref. 15)], this ultranarrow Er-1 atomiclike PL spectrum could offer a significant increase for gain coefficient, of up to 3 orders of magnitude (≈30 meV/8 µeV). Therefore, investigation of optical gain in the Si/Si:Er multinanolayer structures is particularly interesting as these materials constitute presently the most advanced form of Er-doped Si.

In this paper, we report on our study of the stimulated emission and the free carrier absorption for the aforementioned Er-1 center-related ultranarrow spectral line at 1.54 μm, using a combination of the variable stripe length (VSL) (Ref. 16) and shifting excitation spot (SES) techniques under pulsed and continuous-wave (cw) excitations. From the observed results we derive the upper limits for the optical gain cross section and gain coefficient.

II. EXPERIMENTAL DETAILS

A. Preparation of samples

The studied Si/Si:Er multinanolayer structures were grown by a sublimation molecular-beam-epitaxy (MBE)
For the optical activation of Er$^{3+}$ ions, the as-grown PL was detected using a monochromator system of 1 m F/8 monochromator samples. The samples were annealed at 800 °C for 30 min in a continuous processing lock-in amplifier detector. The PL signal was filtered and amplified via digital signal processing.

The 1.5–300 K temperature range. Electronic signals from the He cryostat were displayed by a 500 MHz oscilloscope.

The purity of Er$^{3+}$ ions in the epitaxial layer was determined by secondary ion mass spectroscopy as cited within the pumped stripe-shaped area of the length $l$.

The VSL technique originally introduced by Shaklee et al. enabled to resolve even a small optical gain under conditions when no net gain can be observed and corrects the signal for most of the possible artifacts. It is also suitable for nonwaveguiding samples. Nevertheless, we feel important to note that VSL-like techniques use “stripe-shaped” pumped area and therefore, for a precise interpretation of the observed results in low-gain materials, laser-induced changes in the refractive index should be taken into account.

In this paper, laser-induced changes in the absorption coefficient are studied using the combination of the VSL and SES. The measurements were conducted at low temperature ($T=4.2$ K) under cw and pulsed laser excitation, both at 532 nm. The cw excitation was provided by a solid-state laser Nd:YVO$_4$ (Spectra Physics) and the pulsed excitation by a third harmonic of a Nd:YAG laser pumping a tunable wave-length optical parametric oscillator (Solar Laser Systems), featuring 5-ns pulses with a repetition rate of 20 Hz. The detection system and cryostat configuration remain the same as for PL measurements.

In the VSL experiment, sample is excited by a homogeneously stripe-shaped intense laser beam [Fig. 1(a)] of a length $l$, formed by a cylindrical lens. In order to achieve a homogeneous excitation, only a part of the Gaussian profile of the excitation beam is used, selected by the slit of 1.2-mm width, placed before the cylindrical lens. The length of the VSL stripe is changed by a moving shield (with a sharp-edge knife) placed on a motorized micropositioner with the resolution of 1.25 μm.

The SES experiment, another blocking shield is introduced to the VSL setup [Fig. 1(b)] in order to create a small rectangular excited spot that can be shifted along the stripe as used in the VSL configuration. The width of the SES spot $x_0$ is equal to the differential shift of the slit in the VSL setup (Fig. 1). In order to minimize the effect of the inevitable laser diffraction on the movable shields on the spot/stripe shape, a double-lens system with the magnification ratio of 2.5:1 was placed in front of the sample. The Er-1 related 1.54 μm PL is detected from the edge of the sample, perpendicularly to the excitation (Fig. 1).

In the SES experiment, PL emerging from the excited spot passes through a nonexcited area of length $l'_k=kx_0$ [Fig. 1(b)], where it can be absorbed by Er-1 centers in the ground state. The signal attenuation is given by the absorption coefficient of Er-1 centers in the ground state $\alpha_0$. Scattering losses as well as absorption of the ultranarrow Er-1 emission line at 1.54 μm by other Er dopants, if any, can be neglected due to their broad absorption spectra.
The detected SES signal follows the Beer-Lambert law

\[ I_k^{\text{SES}} = I_{SpE} e^{-\alpha_{ind}x_k}, \]

where \( I_{SpE} \) stands for the spontaneous emission intensity per unit length.

Let us now discuss the situation, when the luminescence passes the system where all the Er-1 centers are in the excited state, which can be realized by measuring the VSL in the saturation regime. Under such conditions, laser-induced absorption coefficient \( \alpha_{ind} \) comprises the optical gain \( g \) (negative absorption coefficient of Er-1 in the excited state) and the free carrier absorption \( \alpha_{FCA} \). The detected VSL signal is given by

\[ I_k^{\text{VSL}} = I_{SpE} \frac{1 - e^{-\alpha_{ind}x_k}}{\alpha_{ind}}, \]

\[ \alpha_{ind} = \alpha_{FCA} - g. \]

The negative value of \( \alpha_{ind} \) would lead to light amplification, defined by the net gain coefficient \( G = |\alpha_{ind}| \). The positive value, on the other hand, would lead to attenuation and could appear in the situation when the free carrier absorption dominates over the stimulated emission (\( \alpha_{FCA} > g \)). Since the free carrier absorption cross section in c-Si at 1.54 \( \mu \)m is known \( |\sigma_{Si}| \approx 10^{-17} \text{ cm}^2 \) (Refs. 24 and 25), one can estimate \( g \) from comparison of measured \( \alpha_{ind} \) and \( \alpha_{FCA} \).

Laser-induced changes in absorption coefficient \( \Delta \alpha = \alpha_{ind} - \alpha_0 \) result in a difference between the as-measured VSL signal \( I_k^{\text{VSL}} \) and the SES signal \( I_k^{\text{SES}} \), integrated over the stripe length \( x_k \)

\[ I_k^{\text{SES}} = \sum_{i=1}^{k} \delta_{i} \].

In saturation (all Er-1 centers in the excited state), the \( \alpha_0 \) magnitude determines the maximal optical gain coefficient \( g = |\alpha_0| \) of the Er-1 center, leading to \( \Delta \alpha = \alpha_{FCA} - 2g \). The magnitude of \( \Delta \alpha \) can be evaluated from comparison of the as-measured SES signal \( I_k^{\text{SES}} \) with the differential VSL signal \( I_k^{\text{VSL}} \)

\[ I_k^{\text{VSL}} = I_k^{\text{VSL}} - I_k^{\text{VSL}-1} = I_{SpE}(e^{-\alpha_{FCA}x_k})_{x_k} \]

leading to

\[ \Delta \alpha = - \frac{\ln(I_k^{\text{VSL}}/I_k^{\text{SES}})}{x_k} = \alpha_{ind} - \alpha_0. \]

In both cases, size of the SES spot must be carefully adjusted to be equal to the VSL differential shift step \( x_0 \) (Fig. 1).

III. EXPERIMENTAL RESULTS

The PL spectrum of the Si/Si:Er multilayer structure, measured at \( T = 4.2 \text{ K} \) under cw 532 nm excitation, is plotted in Fig. 2(a). The spectrum features few intense lines (indicated by the arrows) and arises from the radiative recombination from the lowest level of the first excited state into the split ground state of Er\(^{3+} \) in the slightly distorted tetrahedral position (inset in Fig. 2(a)). In this study we concentrate on the nonlinear optical properties of the ultranarrow Er-1 center emission peak at \( 1.54 \text{ \( \mu \)m} \) [Fig. 2(b)].

Prior to the nonlinear absorption coefficient investigations, the excitation beam profile and equality of the SES spot size with the VSL differential shift has been verified (to avoid an overlap or a gap between the SES spots). For this purpose, a power meter has been placed immediately after the movable shields and signals at the excitation wavelength of 532 nm have been measured in the SES and VSL configurations (Fig. 3). The integrated SES \( I_k^{\text{SES}} \) and the as-measured VSL signal \( I_k^{\text{VSL}} \) of the laser beam in Fig. 3 are identical, which confirms equality of the SES spot size \( (x_0^{\text{SES}}) \) and the differential VSL shift step \( (\delta^{\text{VSL}} = x_0^{\text{SES}} = x_0^{\text{VSL}}) \) (Fig. 1) and validates the experimental procedure. The as-measured SES signal in Fig. 3 copies the excitation beam profile. However, as mentioned before, in the optical gain experiment only a short central part of the beam, of a width of \( \sim 2 \text{ mm} \) and a flat profile, has been used (additional slit) in order to achieve a homogeneous excitation beam profile.

Also a possible effect of the focal point of the PL collecting lenses has been considered. To ensure the constant efficiency of the detection over the whole stripe length (<1.5 mm), a large monochromator detection slit of 2 mm was used. Moreover, the change in the detected signal intensity with a slight (\( \pm 1 \text{ mm} \)) shift of the objective lens has been checked and found to be negligible. That is understandable, since the objective lens numerical aperture is small (NA \( = 0.24 \)). Moreover, this effect is automatically corrected in the SES and VSL comparison.

As discussed above, the signals of the integrated SES and VSL should match each other in the case that \( \Delta \alpha = 0 \). We note, however, that in spite of this careful calibration, a difference between VSL and SES experiments with Er-1 emission may still appear not necessarily due to the nonlinear effects. In particular, some electrons and holes generated within the illuminated spot can diffuse out of the excitation region, contributing additional Er-1 luminescence. Such a situation is especially plausible at higher excitation fluxes. Consequently, the integrated SES signal might be overestimated. This experimental artifact can mask a small optical
gain, which might actually appear in the case that equal SES and VSL signals are being measured. However, it is important to note that this effect can lead to a possible underestimation of the gain coefficient and never to an overestimation.

In Figs. 4(a)–4(d) we show a comparison of the as-measured VSL and SES signals with the integrated SES and differential VSL signals, measured at 1.54 μm Er-1-related emission for different excitation flux under [(a) and (b)] cw and [(c) and (d)] pulsed excitation at 532 nm. Measurements were done at low temperature $T=4.2$ K.

IV. DISCUSSION

Laser-induced changes in absorption coefficient $\Delta \alpha$ were evaluated using Eq. (5) from comparison of the as-measured SES and the differential VSL signal. The result is plotted in Figs. 5(a) and 5(b).

Since the laser-induced absorption coefficient $\alpha_{\text{rad}}$ strongly depends on the excitation conditions, measurements were done for various excitation fluxes in pulsed and cw regimes. In particular, in order to reach the upper gain limit condition, the saturation of PL must be achieved. Therefore, high pump fluxes $\Phi$, on the order of $3 \times 10^{18} - 2 \times 10^{20}$ photons cm$^{-2}$ s$^{-1}$, were applied for the cw excitation [Fig. 5(a)] and $7 \times 10^{23} - 5 \times 10^{24}$ photons cm$^{-2}$ s$^{-1}$ for the pulsed excitation [Fig. 5(b)], both at 532 nm. Experiments were done also under different excitation wavelengths (469, 489, 630 nm) in pulsed regime. Since the observed results are very similar, we do not present these data here.

As mentioned before, stimulated emission at 1.54 μm in our system competes with high free carrier absorption $\alpha_{\text{FCA}}$. Under high cw excitation flux, the free carrier absorption is maximal, as is the effect of the optical gain. In Figs. 4(a) and 4(b) we show the VSL and SES data measured under such a condition. It can be clearly seen that the integrated SES signal is higher than the corresponding VSL signal. This difference increases with higher flux and longer stripe length. Similar behavior has been observed also for different pump fluxes (data not presented). This implies that laser-induced losses dominate, i.e., $\Delta \alpha > 0$ (Fig. 5).

In order to evaluate the laser-induced absorption cross-section, kinetic model for concentration of free carriers (including free excitons) $n$ in a system of silicon and erbium is used

$$\frac{dn(t)}{dt} = n - \frac{n}{\tau_{\text{FC}}},$$

$$\tau_{\text{FC}} = \tau_{\text{trap}} + \tau_{\text{rad}} + \tau_{\text{Auger}}^-.$$  

Here $\alpha$ stands for the absorption coefficient of the system at the excitation wavelength; $\tau_{\text{trap}}$ is the trapping rate; $\tau_{\text{rad}}=n\beta$ is the radiative recombination rate given by the radiative coefficient $\beta$ [in crystalline silicon $\sim 1.1 \times 10^{-14}$ cm$^3$ s$^{-1}$ (Ref. 26)]; $\tau_{\text{Auger}}^- = n^2 \gamma$ stands for the Auger recombination rate given by Auger coefficient $\gamma$ [in crystalline silicon $\sim 2.8 \times 10^{-31}$ cm$^6$ s$^{-1}$ (Ref. 27)]. The thermal generation of free carriers is neglected since the VSL and SES measurements were performed at $T=4.2$ K.

Under cw excitation, Eq. (6) can be solved for the steady-state condition. Moreover, high flux regime leads to saturation of trapping to Er and other possible defect states. Also radiative transitions in this structure can be neglected compared to the nonradiative Auger recombination, simplifying the Eq. (6) to $(dn/dt)=0 = (\alpha \Phi - n^3 \gamma)$ and leading to a cubic-root dependence of the free carrier density on the pump flux:

$$n_{\text{cw}} = \left(\frac{3}{\alpha \beta \Phi} \right)^{1/3}.$$  

(7)

The coefficient of the laser-induced changes in absorption $\Delta \alpha$ is given as

$$\Delta \alpha = \sigma n.$$  

(8)

Using the Eqs. (7) and (8) and the known value of absorption of c-Si at the excitation wavelength $\alpha_{\text{c-Si}} = 6800$ cm$^{-1}$,28 we obtain laser-induced absorption cross section $\sigma_{\text{c-Si}} = (1.12 \pm 0.06) \times 10^{-17}$ cm$^2$ [fit in Fig. 5(a)]. This value is in excellent agreement with the usually observed free carrier cross section in c-Si $\sigma_{\text{c-Si}} \sim 10^{-17}$ cm$^2$.24,25 implying that the gain (if any) is much smaller. Therefore we can
conclude that in order to enhance the effect of stimulated emission, free carrier effects must be drastically lowered.

In order to lower $\alpha_{FCA}$, a short pulsed laser excitation would be advantageous. The pulse duration $t_p$ should be smaller than Er-1 related luminescence decay time and free carriers lifetime $\tau_{FC}$. In the pure c-Si at cryogenic temperatures, $\tau_{FC}$ can be as high as 1 ms, which is comparable to the luminescence lifetime of Er-1 center. However, in highly doped silicon, trapping radically reduces $\tau_{FC}$ to the nanosecond range. The exciton lifetime (at $\sim$1.14 $\mu$m) in our Si/Si:Er multilayer structure was measured to be 150 ns by photon counting method (data not shown) at low temperature ($\sim$15 K, closed-cycle cryostat).

The VSL and SES data, measured with the pulsed excitation ($t_p$=5 ns), are plotted in Figs. 4(c) and 4(d). The evaluated $\Delta \alpha$ given in Fig. 5 is lower than that measured with cw excitation (note the different excitation photon flux).

The solution of Eq. (6) for short ($t_p \ll \tau_{FC}$) intense pulses leads to a simple linear dependence

$$ n_{pulse} = \alpha_{FCA} t_p. $$ (9)

The linear fit of the laser-induced losses $\Delta \alpha$ on the excitation photon flux in Fig. 5(b), using Eq. (9), leads to $\sigma_{pulse}=(8.6 \pm 1.7) \times 10^{-21}$ cm$^2$.

Assuming that only the free carrier losses are present, losses induced under excitation flux used in pulsed experiment should be several orders of magnitude higher than experimentally measured [Fig. 5(b)]. However, $\sigma_{pulse}$ is significantly lowered, compared to $\sigma_{cw}$. This can be related to the short free carrier lifetime, compared to the Er-1 related luminescence, which makes the free-carriers effects to become negligible under the pulsed excitation, compared to the cw excitation.

The sketch of the interplay between the free carriers and Er-1 luminescence lifetimes is shown in Fig. 6. Under pulsed excitation, the effect of the optical gain is greatly enhanced, lowering the measured induced absorption cross section from expected $\sigma_{Si} \sim 10^{-17}$ cm$^2$ down to $\sigma_{pulse}=(8.6 \pm 1.7) \times 10^{-21}$ cm$^2$. Optical gain cross section in our system from Er-1 related emission can then be estimated as $\sigma_{gain}=\sigma_{Si} - \sigma_{pulse} \approx 10^{-17}$ cm$^2$. Under the given experimental conditions, when all optically active Er-1 centers are in the excited state, $\sigma_{gain}$ represents the upper limit of the optical gain. Considering the concentration of the optically active Er dopants (Er-1 centers) of $\sim 8 \times 10^{17}$, we achieve the upper limit of the optical gain coefficient $g=8.8$ cm$^{-1}$. If all free carrier absorption losses could be eliminated, this would correspond to a net gain coefficient $G$ of 38.2 dB cm$^{-1}$. Compared to the value estimated in Ref. 23 ($g=22$ dB cm$^{-1}$ expected for Er concentration of 10$^{19}$ cm$^{-3}$), we achieved nearly 20 times higher value. This is reasonable, since Ref. 23 (i) gives the lower limit and (ii) the investigated Er emission was inhomogeneously broadened. On the other hand, our estimate is lower than could be expected from linewidth comparison ($\sim 10^3$).

While the upper limit of the optical gain cross section is reasonably high, free carrier losses exceed the stimulated emission effect even at the optimum conditions, such as ultranarrow emission line, cryogenic temperature, saturation regime, and short pulse excitation. Therefore we conclude that net optical gain in Er-doped silicon will only be possible if the free carrier losses will be severely suppressed. One possibility to achieve that could be by an application of electric field to drive away free carriers immediately after excitation of Er$^{3+}$ ions, i.e., following a strategy similar to that used in Ref. 1.

V. CONCLUSION

The present study demonstrates that comparison of differential VSL and as-measured SES signal can be used for determination of laser-induced absorption cross section. This technique was applied to study optical gain and free carrier absorption at Er-1 related ultranarrow emission line at 1.54 $\mu$m in MBE grown Si:Er material. Under high flux cw excitation, when the free carrier effects are maximal, the measured laser-induced absorption cross section at 1.54 $\mu$m agreed well with that commonly reported for free carriers in c-Si. Under pulsed excitation, on the other hand, free carrier effects are minimized while stimulated emission remains intact. Under such conditions, considerable lowering of the laser-induced absorption cross section has been observed. From that the upper limit of optical gain in Er-doped silicon was estimated as 8.8 cm$^{-1}$. We conclude that free carrier influence must be drastically lowered if net gain is to be achieved in c-Si:Er.
